classes were subsequently identified, namely, K (Kappa; the mitochondrial form), S (Sigma), Z (Zeta), and O (Omega) (Hayes and Pulford, 1995; Whalen and Boyer, 1998; Strange *et al.*, 2000; Hayes *et al.*, 2005; Higgins and Hayes, 2011; Oakley, 2011). None of these 8 gene classes corresponds to the microsomal GSTs, which appear to have evolved independently. By definition, the subunits in the different classes share less than 50% amino acid sequence identity. Generally, the subunits within a class are ~70% identical, but can share up to 90% sequence identity, and can form heterodimers, whereas the subunits in different classes are generally only ~30% identical. On the basis of structural similarity as well as the residues in the GSH-binding site that are involved in thiolate anion formation, the cytosolic GSTs can be divided

into two groups: the more recently evolved Alpha, Mu, Pi, and Sigma classes that use a tyrosine residue near the N-terminus to activate GSH; and the older Theta, Omega, and Zeta classes that use either an N-terminal proximate serine or cysteine residue to activate GSH (Higgins and Hayes, 2011). Members of the Alpha and Mu classes can also form heterodimers with each other (Hayes *et al.*, 2005). Affinity labeling studies with rat Alpha GSTs demonstrated the presence of a high-affinity, nonsubstrate binding site within the cleft between the two subunits of the dimer. Presumably, the cleft in heterodimers would be different from that in homodimers, which suggests the possibility that there is an evolutionary reason that the formation of heterodimers between Alpha and Mu subunits has been conserved (Hayes *et al.*, 2005).

Several GSTs are overexpressed in various cancers, such as Alpha, Mu, Theta, Pi, and microsomal GSTs, which can confer resistance against many chemotherapeutic agents. For example, GST Alpha overexpression has been correlated with resistance to alkylating agents (Sau *et al.*, 2010). GST Mu overexpression is associated with chlorambucil resistance and a poor prognosis in childhood acute lymphoblastic leukemia (Sau *et al.*, 2010). The microsomal GSTs have been shown to confer resistance to chlorambucil, melphalan, cisplatin, and doxorubicin treatment (Sau *et al.*, 2010). GSTP1-1 overexpression, the most highly expressed GST in various cancers, is often associated with a poor prognosis and chemotherapeutic resistance in ovarian, non-small cell lung, breast, and colorectal cancers (Sau *et al.*, 2010; Tew and Townsend, 2011). Two strategies have been adopted in the development of cancer therapies that specifically target cells that overexpress GSTs, namely (1) inhibition of GSTs and (2) activation of prodrugs by GSTs to form reactive metabolites. Telintra™ (TLK199; Ezatiostat—not yet approved) is a GSH-peptidomimetic prodrug that is activated by cellular esterases to the selective GSTP1-1 inhibitor TLK117 (Sau *et al.*, 2010; Tew and Townsend, 2011). Although not commonly used due to its diuretic effects, ethacrynic acid inhibition of GSTs sensitizes cancer cells to chemotherapeutics (Sau *et al.*, 2010). A synthetic GSH analog specifically inhibits GSTA1-1, whereas the 7-nitro-2,1,3-benzoxadiazole derivative, NBDHEX, is an inhibitor of GSTP1-1 that is not effluxed by transporters (Sau *et al.*, 2010). Several other drugs have been shown to inhibit GSTs, such as drugs that act as NO donors (PABA/NO and oxathiazolylum-5-olate derivatives) and bombesin-sulfonamide derivatives (Sau *et al.*, 2010). Telcya™ (TLK286; canfosamide—not yet approved) is a modified GSH analog that can be metabolized by GSTP1-1, which results in the release of two electrophilic fragments, GSH vinyl sulfone and a tetrakis (chloroethyl) phosphorodiamidate that leads to apoptosis (Townsend and Tew, 2003; Rosen *et al.*, 2004; Gonzalez and Tukey, 2006; Tew and Townsend, 2011). Other drugs have also been developed to take advantage of activation by GSTs, such as 2-crotonyloxymethyl-2-cycloalkenone (COMC) derivatives, brostallicin and ethacraplatin (Sau *et al.*, 2010).

As is the case with many of the other xenobiotic-metabolizing enzymes, all of the GST enzymes are polymorphic and this likely contributes to interindividual differences in drug response or toxicity. For example, the null phenotypes for GST Mu and GST Theta, GSTM1*0 and GSTT1*0, respectively, contribute to the drug-associated toxicities of several xenobiotics, such as carbamazepine, valproic acid, and troglitazone (Saruwatari *et al.*, 2010; Ikeda, 2011). Therefore, individuals who are polymorphic for these enzymes (and also potentially for other GST allelic variants) are at an increased risk of toxicity by xenobiotics that are selectively biotransformed by specific GSTs.

The alpha GSTs are the major GSTs in liver and kidney. They have basic isoelectric points. The rat genome database (<http://rgd.mcw.edu>) indicates that rats express at least four GSTA genes, GSTA1, GSTA2, GSTA3, and GSTA4 (provisional). Humans express five subunits belonging to the Alpha class of GSTs, designated GSTA1 to GSTA5. Human GSTA1 and GSTA2 are polymorphic, with at least two and five alleles identified, respectively, which affect the amount or the activity of expressed protein (Hayes *et al.*, 2005). GSTA1*A expression is higher than GSTA1*B, and individuals with the latter loss-of-function variant have improved rates of breast cancer survival, presumably due to increased efficacy of chemotherapeutic drugs (Ekhart *et al.*, 2009). On the other hand, GSTA2 variants *A to *D do not show much difference in enzymatic activity, whereas GSTA2*E is a

loss-of-function variant (McIlwain *et al.*, 2006). Rats express at least 7 functional Mu subunits, designated GSTM1 to 7. Humans express 5 subunits belonging to the Mu class of GSTs, designated GSTM1 to 5. Human GSTM1, 3, and 4 are known to be polymorphic. In the case of GSTM1, the *A and *B allelic variants differ by a single amino acid; *A is a “basic variant” with lysine at residue 173, whereas *B is an “acidic variant” with asparagine at the corresponding site. There is also a GSTM1 deletion (*0) and a duplication (*1 × 2) (Hayes *et al.*, 2005). The incidence of the GSTM1 deletion is high in Pacific Islander and Malaysian populations (ie, 62%–100%), intermediate in several other populations (ie, 35%–62% in those of European descent; 32%–53% in those of Asian descent; 40%–53% in those of Hispanic descent), and low in those of African descent (ie, 23%–41%) (Geisler and Olshan, 2001; Piacentini *et al.*, 2011). GSTM1*0 has only a modest effect on the incidence of lung, head, and neck cancers consistent with its high prevalence in various populations. The GSTM1*0 polymorphism has been linked to an increased susceptibility to certain inflammatory diseases (eg, asthma) (Hayes *et al.*, 2005). At least two allelic variants of GSTM3 and GSTM4 have also been identified. Members of the Mu class of GSTs have neutral isoelectric points. Human GSTM2 and M3 are expressed in muscle and brain, respectively. The GSTM1*0 polymorphism is a risk factor for carbamazepine and valproic acid hepatotoxicity, whereas the double null phenotype of GSTM1*0 and GSTT1*0 is a risk factor for troglitazone hepatotoxicity (Saruwatari *et al.*, 2010; Ikeda, 2011).

Humans and rats express one subunit belonging to the Pi class of GSTs, GSTP1, whereas mice have been found to express two Pi subunits, GSTP1 and GSTP2 (provisional). The human Pi enzyme is polymorphic, with at least 4 allelic variants reported (Hayes *et al.*, 2005). The subunit encoded by GSTP1*B is 7 times more active than that encoded by GSTP1*A in conjugating diol epoxides of polycyclic aromatic hydrocarbons (PAHs) (Strange *et al.*, 2000). GSTP polymorphisms are known to influence susceptibility to carcinogens (including some pesticides), affect the response to chemotherapy used in the treatment of metastatic colon cancer and multiple myeloma, and modify the risk of acute myeloid leukemia which results from the successful treatment of Hodgkin's disease, non-Hodgkin's lymphoma, breast, and ovarian cancer (Hayes *et al.*, 2005; Liu *et al.*, 2006b). GSTP polymorphisms that result in decreased activity have been implicated in an increased susceptibility to certain inflammatory diseases (eg, asthma) (Hayes *et al.*, 2005). Members of the Pi class of GSTs have acidic isoelectric points. They are expressed in the placenta, lung, gut, and other extrahepatic tissues. In rats, GSTP1 is one of several proteins (so-called preneoplastic antigens) that are overexpressed in chemical-induced tumors.

The Sigma class of GSTs is widely distributed in nature, and is present in many species including humans, mice, rats, chickens, insects, flatworms, and mollusks (Flanagan and Smythe, 2011). Sigma GSTs, also known as hematopoietic prostaglandin D synthases (HPGDS), are involved in the synthesis of prostaglandin in mammals, and catalyze the conversion of the cyclooxygenase product PGH₂ to PGD₂. Sigma subunits are also capable of conjugating GSH to a variety of aryl halide substrates and organic isothiocyanates and also have GPX activity toward cumene hydroperoxide (Flanagan and Smythe, 2011). The human Sigma class GST (HPGDS) is different from other cytosolic GSTs in that it is activated by divalent metal ions, such as Mg²⁺ and Ca²⁺, binding at the center of the dimer interface formed by a group of 6 conserved Asp residues (Inoue *et al.*, 2003; Flanagan and Smythe, 2011). Rats and humans appear to express a single Sigma GST (GSTS1, also known as the GSH-dependent HPGDS). The tissue distribution

of Sigma GST occurs in a species-specific manner. In mammals, high levels of Sigma GST are present in the spleen, bone marrow, placenta, lung, adipose, oviduct, and both dermal and epidermal layers of skin (Flanagan and Smythe, 2011). In rats, Sigma GST is highly expressed in bone marrow and spleen, whereas in humans it is highly expressed in adipose tissue, placenta, lung, and fetal liver (Flanagan and Smythe, 2011). Immunohistochemical studies of Sigma GST (ie, HPGDS) in rat, mouse, and human have shown that expression of the enzyme is limited to select cell types, namely, antigen-presenting cells, resident tissue and infiltrating mast cells, and T-helper (Th)-2 cells (Flanagan and Smythe, 2011). Sigma GST can play multiple roles in the immune response because the PGD₂ produced by Sigma GST (ie, by HPGDS) can exert both proinflammatory and anti-inflammatory effects (Flanagan and Smythe, 2011). To block PGD₂ production associated with allergic inflammation, drugs have been or are currently being developed as Sigma GST (HPGDS) inhibitors, such as tranilast (*N*-(3,4-dimethoxycinnamoyl)anthranilic acid), which is an inhibitor of both HPGDS and LPGDS (lipocalin prostaglandin D synthase) (Flanagan and Smythe, 2011). At least 2 allelic variants of Sigma GST (HPGDS) have been identified, but their functional significance remains to be elucidated (Hayes *et al.*, 2005).

Humans express two subunits belonging to the Theta class of GSTs (GSTT1 and GSTT2), whereas rats and mice each express 4 subunits (GSTT1-4). GST Theta catalyzes the conjugation of mono and dihaloalkanes with GSH, in contrast to α -haloalkanoates and α,α -dihaloalkanoates which tend to be substrates of GST Zeta (Josephy, 2010). Due to the small active site of GST Theta, small xenobiotics are typical substrates of this enzyme, such as dichloromethane (Josephy, 2010). Additionally, analogous to the reaction shown in Fig. 6-20, GSTT-1 is involved in the bioactivation of ethylene dibromide (an insecticide and gasoline additive) to an electrophilic sulfonium ion that can form adducts with macromolecules (Josephy, 2010). A GSTT1 deletion has been identified (GSTT1*0), which has a modest effect on the incidence of lung, head, and neck cancers, and has also been implicated in an increased susceptibility to certain inflammatory diseases (eg, asthma) (Hayes *et al.*, 2005). The incidence of the GSTT1*0 is present in several populations, at a low to intermediate frequency (10%–43%) in those of European and Mediterranean descent and a slightly higher frequency (20%–45%) in those of African descent (Piacentini *et al.*, 2011). The GSTT1 null allele, in conjunction with GST Mu deficiency, predisposes to troglitazone hepatotoxicity (Ikeda, 2011). Human GSTT2-2 conjugates ethacrynic acid with GSH and catalyzes the GSH-dependent reduction of cumene hydroperoxide, as well as the GSH-dependent sulfatase activity of 1-menaphthyl sulfate (Higgins and Hayes, 2011).

Zeta class GSTs are found in many species, such as plants, fungi, and mammals. Within mammals, there is also a wide tissue distribution of the protein with high levels predominantly in the liver and kidney (Board and Anders, 2011). A single Zeta subunit is expressed in rats, mice, and humans (GSTZ1), which dimerizes to form the functional enzyme GSTZ1-1. GSTZ1-1 is the same enzyme as maleylacetoacetate isomerase (MAAI), the enzyme that catalyzes the isomerization of maleylacetoacetate to fumarylacetoacetate, the penultimate step in tyrosine and phenylalanine catabolism (Board and Anders, 2011). GSTZ1-1 also catalyzes the GSH-dependent biotransformation of dichloroacetate (DCA) to glyoxylate ($\text{CHCl}_2\text{-COOH} \rightarrow \text{CHO-COOH}$) (Board and Anders, 2011). Although GSH is required for the biotransformation of DCA to glyoxylate, it is not consumed as the GSTZ1-1-catalyzed nucleophilic attack of GSH on DCA yields *S*-(α -chlorocarboxymethyl)glutathione (GS-CHCICOOH), which in turn undergoes dehalogenation and

facile hydrolysis to produce glyoxylate and GSH (Board and Anders, 2011). In rats, DCA irreversibly inhibits GSTZ1-1 through covalent modification of Cys₁₆ by *S*-(α -chlorocarboxymethyl)glutathione (Board and Anders, 2011). While monohaloalkanes and dihaloalkanes tend to be substrates for GST Theta, a number of α -haloalkanoates and α,α -dihaloalkanoates have been identified as substrates for GSTZ1-1 (Board and Anders, 2011). At least 4 polymorphic variants of GSTZ1-1 have been identified in humans, with the haplotypes designated as GSTZ1A (Lys₃₂, Arg₄₂, Thr₈₂), GSTZ1B (Lys₃₂, Gly₄₂, Thr₈₂), GSTZ1C (Glu₃₂, Gly₄₂, Thr₈₂), and GSTZ1D (Glu₃₂, Gly₄₂, Met₈₂) (Board and Anders, 2011). GSTZ1C shows the highest allele frequency and has been designated the wild-type enzyme. GSTZ1A shows the highest rate of conversion of DCA to glyoxylate and is resistant to inactivation by DCA (Board and Anders, 2011). Genetically determined differences in DCA turnover may be significant if DCA is utilized in cancer therapy (Michelakis *et al.*, 2010; Board and Anders, 2011). GSTZ1 knockout mice have increased levels of GSTA1, A2, M1, M5, P1, P2, and NQO1 in the liver, and undergo rapid weight loss, leucopenia, and death when provided 2% phenylalanine in drinking water (recall that GSTZ1-1 is the same enzyme as MAAI, the enzyme that catalyzes the isomerization of maleylacetoacetate to fumarylacetoacetate, the penultimate step in tyrosine and phenylalanine catabolism) (Board and Anders, 2011).

The Omega class of GST was initially identified through bioinformatics analysis of the expressed sequence tag (EST) database. Omega GSTs are present in many species including plants, yeast, nematodes, insects, and mammals (Board, 2011). Two Omega subunits have been identified in mice, rats, and humans (GSTO1 and GSTO2). GSTO1 and GSTO2 are also expressed strongly in mouse liver, heart, and kidney with wide distribution in other tissues (Board, 2011). The GSTOs differ from the other cytosolic GSTs in that they do not display the typical activity toward substrates such as 1-chloro-2,4-dinitrobenzene, dichloromethane, cumene hydroperoxide, or ethacrynic acid, but have some characteristics of glutaredoxins (GLRXs) (Mukherjee *et al.*, 2006; Board, 2011). Interestingly, a mutation in GSTO1 (Cys₃₂Ala) significantly improves its GSH-conjugating activity with 1-chloro-2,4-dinitrobenzene (Board, 2011). Human GSTO1 shows thiol-transferase activity and can catalyze the reduction of *S*-phenacylglutathione (a metabolite of tear gas), dehydroascorbate, and methylated arsenic species (Board, 2011). The major component in tear gas 2-chloroacetophenone is converted to a GSH conjugate ($\text{phenyl-CO-CH}_2\text{Cl} + \text{GSH} \rightarrow \text{phenyl-CO-CH}_2\text{-SG} + \text{HCl}$) that is further metabolized by GSTO1 to acetophenone ($\text{phenyl-CO-CH}_2\text{-SG} + \text{GSH} \rightarrow \text{phenyl-CO-CH}_3 + \text{GSSG}$) (Board, 2011). Inasmuch as the reaction with *S*-phenacylglutathione is highly specific to GSTO1, a novel substrate was developed, namely, *S*-(4-nitrophenacyl)glutathione, that can be used in spectrophotometric assays to determine GSTO1 activity (Board, 2011). GSTO2 also exhibits thiol-transferase activity and can catalyze the reduction of monomethylarsenate and dehydroascorbate, but not *S*-phenacylglutathiones (Board, 2011). Sulfonylurea cytokine-release inhibitory drugs (CRIDS) can bind to GSTO1 and inhibit IL-1 β activation, suggesting GSTO1 involvement in a proinflammatory response (Board, 2011). This suggests that inhibition of GSTO1 is a potential therapeutic target to treat inflammation (Board, 2011). Other agents have been shown to inhibit GSTO1 activity, such as tocopherol succinate, phenylsulfonate, omeprazole, and rifampicin (Bachovchin *et al.*, 2009; Board, 2011). As Omega GSTs can reduce monomethylarsenic acid, they have been suggested to play a key role in arsenic biotransformation through the arsenic methylation pathway (Board, 2011). However, several studies have

not supported a major role for GSTOs in overall arsenic biotransformation (Board, 2011). Whereas most GSTs have a tyrosine or serine at the active site, GSTOs have a cysteine and an additional 19 amino acids at the N-terminus (Mukherjee *et al.*, 2006; Board, 2011). Many polymorphisms have been detected in both GSTO1 and GSTO2, with 5 and 4 polymorphisms that result in amino acid changes, respectively (Mukherjee *et al.*, 2006; Board, 2011). GSTO genes have also been associated with several neurological diseases, suggesting that variation of these GSTs may modify disease susceptibility or age of onset through a common pathological mechanism (Board, 2011).

The Kappa class of GSTs is an ancient protein family and represents a separate evolutionary pathway that has significant differences in function, localization, and structure than other soluble GSTs (Morel and Aninat, 2011). Harris *et al.* (1991) initially discovered and isolated GST Kappa from rat liver mitochondrial matrix. The Kappa subunit is a soluble, dimeric protein with a 36% sequence identity to GST Theta, and localized to both the mitochondria and peroxisomes (Morel and Aninat, 2011). A single Kappa subunit is expressed in mouse, rat, and humans, with the gene designated as GSTK1 in each species. The 3-dimensional structure of the Kappa subunit is more similar to bacterial GSH-dependent and disulfide-bond-forming oxidoreductase (DsbA) than to the cytosolic GSTs. The Kappa subunit contains a thioredoxin-like domain but with a DsbA-like α -helical domain inserted between the $\alpha 2$ helix and the $\beta 3$ strand (Oakley, 2011). GSTK1 is ubiquitously expressed in humans with kidney, liver, adrenal gland, and adipose tissue expressing the most abundant levels (Morel and Aninat, 2011). Differential expression of GSTK1 has been seen between fetal and adult liver and brain tissues, indicating possible ontogenic regulation of GST Kappa (Morel and Aninat, 2011). In rodents it is present at high levels in the liver and stomach; moderate levels in the kidney, heart, and lung; and subsequent decreasing levels in the duodenum, jejunum, and ileum (Thomson *et al.*, 2004; Knight *et al.*, 2007; Morel and Aninat, 2011). GSTK1 expression in the heart shows marked gender differences, with females expressing twice as much Kappa subunit than males (Knight *et al.*, 2007; Morel and Aninat, 2011).

Two human single nucleotide polymorphisms (SNPs) of GSTK1 have been identified in the 5'-flanking region of the GSTK1 gene located -1308 and -1032 bp from the transcription start site (Shield *et al.*, 2010; Morel and Aninat, 2011). The -1308 SNP corresponds to a G to T transition, whereas the -1032 SNP corresponds to an alteration in a CpG methylation site (Shield *et al.*, 2010; Morel and Aninat, 2011). The T allele variant (-1308 SNP) occurs with a 20% frequency in Asian populations (Morel and Aninat, 2011). The -1032 SNP has been demonstrated to cause a 38% decrease in GSTK1 promoter activity in HEK293 and HepG2 cells (Shield *et al.*, 2010; Morel and Aninat, 2011). GSTK1 expression has been correlated with obesity; hence, GST Kappa may represent a new target for xenobiotics in the treatment of insulin resistance and related metabolic disorders (Morel and Aninat, 2011).

The microsomal GSTs are distinct from the soluble enzymes and have been referred to as the membrane associated proteins in eicosanoid and glutathione metabolism (MAPEG) (Higgins and Hayes, 2011). Six human microsomal GSTs divided into 3 clans have been identified (see Table 6-20), which differ in their ability to form aggregates. For instance, MGST1 exists as a trimer, as does the other clan 2 MAPEG, namely, PGES1, whereas the clan 1 MAPEGs, LTC₄S and MGST2, as well as the clan 3 MAPEG 5-lipoxygenase-activating protein (FLAP), can function as monomers, dimers, trimers, or more complex aggregates (Hayes *et al.*, 2005; Martinez Molina *et al.*, 2008; Higgins and Hayes, 2011).

MGST1 conjugates xenobiotics with GSH and probably functions solely as a detoxication enzyme. It is a highly abundant microsomal protein (1% of total ER protein) in human liver and the outer mitochondrial membrane (5% of outer mitochondrial membrane protein) in rat liver (Morgenstern *et al.*, 2011). MGST1 plays a role in the biotransformation of certain lipophilic reactive electrophiles and the reduction of membrane-embedded hydroperoxides with substrates that include halogenated hydrocarbons and phospholipid hydroperoxides (Morgenstern *et al.*, 2011). The denitration of glyceryl trinitrate is another role for MGST1 (Morgenstern *et al.*, 2011). While no specific substrates for MGST1 have been found, this MAPEG can be selectively activated with *N*-ethylmaleimide to determine its contribution toward overall GST activity (Morgenstern *et al.*, 2011). Furthermore, MGST1 is the only GST that can utilize *N*-acetyl-L-cysteine as a cofactor instead of GSH (Morgenstern *et al.*, 2011). MGST1 is involved in the formation of the mitochondrial permeability transition (MPT), suggesting a role for MGST1 in mitochondria-mediated cell death (Aniya and Imaizumi, 2011). It is also upregulated in many tumor types, overexpressed in many stem cells and stem-cell-like tumor cells, where it may be playing a protective role for these cells (Morgenstern *et al.*, 2011). Other MAPEGs, such as MGST2 and 3, contribute to detoxication and synthesis of leukotriene C₄ (Hayes *et al.*, 2005). FLAP does not have catalytic activity, but binds arachidonic acid and is essential for leukotriene synthesis. LTC₄S and PGES1 do not appear to be involved in xenobiotic metabolism (Hayes *et al.*, 2005). Many SNPs have been identified in MGST1 and FLAP as well as diallelic variants in MGST3 in certain populations, but the biological significance has not yet been determined (Hayes *et al.*, 2005).

The conjugation of certain xenobiotics with GSH is catalyzed by most classes of GST. For example, members of the Alpha, Kappa, Mu, and Pi classes of human cytosolic GSTs, as well as several of the MAPEG GSTs, all catalyze the conjugation of 1-chloro-2,4-dinitrobenzene. Other reactions are fairly specific for one class of enzymes (Hayes and Pulford, 1995). For example, the Alpha GSTs preferentially isomerize Δ^5 steroids to Δ^4 steroids and reduce linoleate and cumene hydroperoxide to their corresponding alcohols. The Mu GSTs preferentially conjugate certain arene oxides and alkene epoxides, such as styrene-7,8-epoxide. The Pi GSTs preferentially conjugate ethacrynic acid. (For additional examples, see Table 6-20.) However, individual members within a class of GSTs can differ markedly in their substrate specificity. In mice, for example, the Alpha GSTs composed of GSTA3 subunits can rapidly conjugate aflatoxin B₁ 8,9-epoxide, whereas those composed of GSTA1 subunits are virtually incapable of catalyzing this reaction (Eaton and Gallagher, 1994).

In rodents, individual members of the Alpha and Mu classes of GSTs are inducible (generally 2- to 3-fold) by 3-methylcholanthrene, phenobarbital, corticosteroids, oltipraz, and various antioxidants (such as ethoxyquin and BHA). Several GST substrates (ie, Michael acceptors) are GST inducers, as are certain nonsubstrates, such as hydrogen peroxide and other ROS (Rushmore *et al.*, 1991; Daniel, 1993; Nguyen *et al.*, 1994; Hayes and Pulford, 1995; Hayes *et al.*, 2005; Higgins and Hayes, 2011). Induction is usually associated with increased levels of mRNA due to transcriptional activation of the gene encoding a subunit of GST. Not all subunits are induced to the same extent (Higgins and Hayes, 2011).

The enhancer regions of the genes encoding some of the rodent GSTs (such as rat GSTA2-2) have been shown to contain a xenobiotic-response element (XRE), a putative phenobarbital-responsive element, a glucocorticoid-responsive element (GRE), and an antioxidant-response element (ARE, which is also known

as the electrophile-responsive element [see Point 9 in the section “Introduction”). Accordingly, in rodents, certain GST subunits are regulated by both AhR and Nrf2 activators (ie, by both *mono-functional* and *bifunctional* agents), as described previously for DT-diaphorase (see the sections “Quinone Reduction—NQO1 and NQO2” and “Induction of Cytochrome P450—Xenosensors”). Induction of GSTs by the Nrf2 activator sulforaphane is thought to be responsible, at least in part, for the anticancer effects of broccoli (Zhang *et al.*, 1992; Higgins and Hayes, 2011). GSTA4 is induced in mice administered α -angeliclactone, butylated hydroxyanisole (BHA), ethoxyquin, indole-3-carbinol, limettin, and oltipraz (Hayes *et al.*, 2005; Higgins and Hayes, 2011). In addition to inducing one or more GSTs, activation of Nrf2 by oxidative stress or exposure to electrophiles induces γ -GCL, which increases GSH levels in response to an initial decrease in GSH levels (see Point 9 in the section “Introduction”).

Factors that regulate the expression of GSTs in rodents may have similar effects in humans, but some differences have been noted. For example, the 5' promoter region of Alpha GST in humans (GSTA1) lacks the ARE and XRE consensus sequences through which the corresponding rat enzyme is induced. However, such sequences appear to be present in the promoter region of human GSTM4 and GSTP1 genes (Hayes and Pulford, 1995; Whalen and Boyer, 1998; Higgins and Hayes, 2011). (A functional ARE is also present in the promoter region of human DT-diaphorase [NQO1].) Therefore, certain subunits of GSTs are inducible by a variety of mechanisms in rats, and other subunits appear to be inducible by similar mechanisms in humans. Species differences in GST regulation may also stem from differences in xenobiotic biotransformation, especially differences in the formation of electrophiles, Michael acceptors, and/or the production of oxidative stress. For example, coumarin is thought to be an inducer of GSTP1 in rats because it is converted in rat liver to reactive metabolites, namely, coumarin 3,4-epoxide and *ortho*-hydroxyphenylacetaldehyde (see Fig. 6-43). In contrast, the major route of coumarin biotransformation in humans is by 7-hydroxylation, which would not be expected to be associated with GST induction.

Conjugation with GSH represents an important detoxication reaction because electrophiles are potentially toxic species that can bind to critical nucleophiles, such as proteins and nucleic acids, and cause cellular damage and genetic mutations. All the enzymes involved in xenobiotic biotransformation have the potential to generate reactive intermediates, most of which are detoxified to some extent by conjugation with GSH. GSH is also a cofactor for GPXs, which play an important role in protecting cells against lipid and hemoglobin peroxidation. Resistance to toxic compounds is often associated with an overexpression of GST. Examples include the resistance of insects to DDT (see Fig. 6-21), of corn to atrazine, and of cancer cells to chemotherapeutic agents.

GST is the major determinant of certain species differences in chemical-induced toxicity. For example, low doses of aflatoxin B₁ cause liver toxicity and tumor formation in rats but not mice, even though rats and mice convert aflatoxin B₁ to the highly reactive 8,9-epoxide at similar rates (this reaction is shown in Fig. 6-34). This species difference arises because mice express high levels of an Alpha class GST (GSTA3) enabling them to conjugate aflatoxin B₁ 8,9-epoxide with GSH up to 50 times faster than rats (or humans, which are also considered a susceptible species) (Eaton and Gallagher, 1994). Mice become sensitive to the adverse effects of aflatoxin B₁ following treatment with chemicals that decrease GSH levels, such as diethyl maleate (DEA) (which depletes GSH) or buthionine-S-sulfoximine (BSO) (which inhibits GSH synthesis). Conversely, treatment of rats with inducers of certain GSTs, such

as ethoxyquin, BHA, oltipraz, and phenobarbital, protects them from the hepatotoxic/tumorigenic action of aflatoxin B₁ (Hayes *et al.*, 1994).

The conjugation of aflatoxin B₁ 8,9-epoxide with GSH provides an interesting example of the stereospecificity with which certain GSH conjugation reactions can occur. CYP converts aflatoxin B₁ to a mixture of *exo*- and *endo*-8,9-epoxides (only a generic 8,9-epoxide is shown in Fig. 6-34, meaning the figure does not indicate whether the oxygen atom is above or below the plane of the ring system). Both enantiomeric epoxides are formed by liver microsomes from mice, rats, and humans, but only the *exo*-epoxide binds extensively to DNA (where it binds to the N⁷ position of guanine). One or more mouse Alpha GSTs rapidly conjugate the *exo*-epoxide, which accounts for the resistance of this species to aflatoxin-induced hepatotoxicity and tumorigenicity (as described above). Rat and human GSTAs do not rapidly conjugate either the *exo*- or the *endo*-epoxide (with the exception of the inducible rat GST, which is not constitutively expressed in rats to any great extent). However, human GSTM1-1 can conjugate aflatoxin B₁ 8,9-epoxide, but it preferentially conjugates the relatively innocuous *endo*-isomer (Wang *et al.*, 2000).

Species differences in the detoxication of aflatoxin B₁ 8,9-epoxide suggest that individual differences in GST may determine susceptibility to the toxic effects of certain chemicals. In support of this interpretation, a genetic polymorphism for GSTM1 has been identified, and individuals who are homozygous for the null allele (ie, those with low GST activity due to complete deletion of the GSTM1 gene) appear to be at a moderately increased risk for cigarette-smoking-induced lung cancer, head and neck cancer, and possibly bladder cancer (Hayes and Pulford, 1995; Whalen and Boyer, 1998; Strange *et al.*, 2000; Hayes *et al.*, 2005). Depending on the ethnic group, 22% to 100% of the population is homozygous for the GSTM1 null genotype, which results in a complete lack of GSTM1 activity in all tissues. On the other hand, there is evidence that GSTM1 confers significant protection from breast cancer in individuals homozygous for a functional GSTM1 allele (Hayes *et al.*, 2005). GSTT1 activity is absent from 11% to 58% of the population (depending on ethnicity) due to deletion of the GSTT1 gene, which appears to increase susceptibility to development of astrocytoma, meningioma, and myelodysplasia. When examined for their individual effect, these null genotypes generally have a small effect on disease susceptibility, with an odds ratio of 2 or less. However, the odds ratio can increase dramatically when these null GST genotypes are examined in conjunction with other genotypes or with environmental factors (such as exposure to carcinogens). For example, when the GSTM1 null genotype is combined with cigarette smoking and a particular CYP1A1 allele, the odds ratio can increase to 8.9 (in one study) or 21.9 (in another study). Polymorphisms that result in amino acid substitutions have been reported for most human GST genes, some of which alter GST function. Some of these polymorphisms may also be risk modifiers for certain diseases in an analogous manner to the GSTM1 and GSTT1 null genotypes.

In some cases, conjugation with GSH enhances the toxicity of a xenobiotic (Monks *et al.*, 1990; Dekant and Vamvakas, 1993; Testa and Krämer, 2008, 2010). Five mechanisms of GSH-dependent activation of xenobiotics have been identified, with the first 4 shown in Fig. 6-67. These mechanisms are (1) formation of GSH conjugates of haloalkanes, organic thiocyanates, and nitrosoguanides that release a toxic metabolite; (2) formation of GSH conjugates of vicinal dihaloalkanes that are inherently toxic because they can form electrophilic sulfur mustards; (3) formation of GSH conjugates of halogenated alkenes that are degraded

Figure 6-67. Role of glutathione conjugation in the activation of xenobiotics to toxic metabolites.

to toxic metabolites by β -lyase in the kidney; (4) formation of GSH conjugates of quinones, quinoneimines, and isothiocyanates that are degraded to toxic metabolites by GGT1 and ANPEP in the kidney; and (5) cyclic GSH conjugation that leads to GSH depletion.

The first mechanism is illustrated by dichloromethane, which is conjugated with GSH to form the highly unstable *S*-chloromethylglutathione, which then breaks down to formaldehyde. Both formaldehyde and the GSH conjugate are reactive metabolites, and either or both may be responsible for dichloromethane-induced tumorigenesis in sensitive species. The rate of conjugation of dichloromethane with GSH is considerably faster in mice, which are susceptible to dichloromethane-induced tumorigenesis, than in rats or hamsters, which are resistant species. Other examples include the 1,1,3,3,3-pentafluoro-2-(fluoromethoxy)prop-1-ene breakdown product of the general anesthetic sevoflurane. This breakdown product and its derivatives are conjugated to GSH, biotransformed to cysteine conjugates and mercapturic acids, which are then converted through β -lyase cleavage and thiol rearrangement to the highly reactive thioacyl fluoride (Testa and Krämer,

2008, 2010). This highly reactive metabolite can form adducts with proteins and may explain its associated nephrotoxicity (Testa and Krämer, 2008, 2010).

The second mechanism accounts for the toxicity of dichloroethane and dibromoethane. These vicinal dihaloalkanes are converted to GSH conjugates that can rearrange to form mutagenic and nephrotoxic episulfonium ions (sulfur half-mustards) (Fig. 6-67). Dichloroethane and dibromoethane can also be oxidized by CYP to chloroacetaldehyde and bromoacetaldehyde (by reactions analogous to those shown in Fig. 6-50). Either pathway can potentially account for the toxic and tumorigenic effects of these dihaloalkanes. However, the toxicity and DNA binding of dihaloalkanes are increased by factors that decrease their oxidation by CYP and increase their conjugation with GSH.

The third mechanism accounts for the nephrotoxicity of several halogenated alkenes. Several halogenated alkenes, such as hexachlorobutadiene, cause damage to the kidney tubules in rats, which leads to carcinoma of the proximal tubules. These nephrotoxic halogenated alkenes are conjugated with GSH and transported to the kidney for processing to mercapturic acids. The cysteine

conjugates, which form by removal of glutamic acid and glycine, are substrates for *N*-acetyltransferase (NAT), which completes the synthesis of mercapturic acids, and cysteine-conjugate β -lyase (CCBL1), which removes pyruvate and ammonia from the cysteine conjugate to produce thionylacyl halides, thiiranes, thiolactones, and thioketenes. The early damage to renal mitochondria caused by halogenated alkenes is probably because CCBL1 is a mitochondrial enzyme.

The fourth mechanism accounts for the nephrotoxicity of bromobenzene, which causes damage to the proximal tubules in rats. Bromobenzene is oxidized by CYP in the liver to bromohydroquinone, which is conjugated with GSH and transported to the kidney (Fig. 6-67). The GSH conjugate is converted to the cysteine derivative by GGT1 and membrane ANPEP. Substitution of bromohydroquinones with cysteine lowers their redox potential and thereby facilitates their oxidation to toxic quinones. The cysteine conjugates of bromohydroquinone are thought to undergo redox cycling and cause kidney damage through the generation of reactive oxygen species (ROS). 4-Aminophenol is thought to cause kidney damage by a similar mechanism, except a benzoquinoneimine is involved in conjugation with GSH and subsequent damage to proximal tubules of the kidney. Treatment of rats with the GSH depletor, buthionine-*S*-sulfoximine (BSO), protects them against the nephrotoxic effects of 4-aminophenol, which implicates GSH conjugation in the activation of this compound.

The fifth mechanism occurs with moderately toxic allyl-, benzyl-, and phenethyl isothiocyanates as well as sulforaphane formed from plant glucosinolates. These compounds are reversibly conjugated with GSH to form thiocarbamates which spontaneously degrade to their isothiocyanates upon export from the cell, which releases GSH. The isothiocyanate is then taken up by the cells again and the cycle can repeat until intracellular GSH is depleted. Once GSH levels are low, the compounds will tend to thiocarbamylate proteins, which can lead to cell death (Hayes *et al.*, 2005).

Thiosulfate Sulfurtransferase (Rhodanese)

Cyanide forms naturally in leucocytes and neural cells, and also as a result of vitamin B₁₂ metabolism, and is also encountered as a xenobiotic in plants containing cyanogenic glycosides, such as cassava, and tobacco smoke (Billaut-Laden *et al.*, 2006). Thiosulfate sulfurtransferase is a mitochondrial enzyme encoded by the TST gene that converts cyanide to the far less toxic metabolite, thiocyanate. The reaction involves transfer of sulfur from thiosulfate (or another sulfur donor) as follows:

The sulfite produced by this reaction can be converted to sulfate by the molybdoenzyme, sulfite oxidase (see the section “Molybdenum Hydroxylases (Molybdoenzymes)”). Cyanide can also be “detoxified” by binding to methemoglobin (the oxidized or ferric form of hemoglobin). 4-Dimethylaminophenol is used to induce methemoglobinemia as an antidote to cyanide poisoning because methemoglobin competes with cytochrome oxidase for the cyanide ion. However, 4-dimethylaminophenol is nephrotoxic to rats, presumably by a mechanism similar to that described above for the structural analog, 4-aminophenol (see preceding section and the section “Glutathione Conjugation”).

In humans, TST is expressed at high levels in the colon, where it plays a major role in the detoxication of hydrogen sulfide (which can reach concentrations of >3 mM) produced by anaerobic bacteria (Billaut-Laden *et al.*, 2006). TST is also widely distributed in

the central nervous system and may also play a role in the import of 5S rRNA into mitochondria (Smirnov *et al.*, 2010). Six allelic variants of TST have been identified, namely, TST*1B to TST*1F and TST*2, with the latter showing significantly reduced intrinsic clearance for thiocyanate formation (Billaut-Laden *et al.*, 2006). TST polymorphisms that decrease cyanide and hydrogen sulfide detoxication may ultimately become important in understanding certain diseases, such as ulcerative colitis and ALS. For instance, hydrogen sulfide release has been found to be 3 to 4 times higher in patients with ulcerative colitis when compared with normal subjects, and is positively correlated with disease severity (Billaut-Laden *et al.*, 2006). Finally, it has been postulated that individuals with ALS display a disorder in cyanide metabolism because of the higher blood and urine levels of cyanide (Billaut-Laden *et al.*, 2006). Mimori *et al.* (1984) also reported significantly decreased TST activity in cervical and thoracic spinal cords of patients with ALS, compared with normal subjects.

Unusual Conjugation Reactions

In rare cases, xenobiotics can be biotransformed to unusual conjugates which can contribute to xenobiotic clearance. As shown in Fig. 6-68, the immunosuppressive drug, 6-mercaptopurine (as well as its precursor azathioprine), is converted to 6-thioinosine monophosphate (TIMP) by hypoxanthine guanine phosphoribosyltransferase (HGPRT) with phosphoribosyl pyrophosphate (PRPP) as the phosphoribosyl donor (Wielinga *et al.*, 2002; Gearry *et al.*, 2010; Hofmann *et al.*, 2012). Similarly to 6-mercaptopurine, 6-thiopurine can also be converted to a thionucleotide monophosphate (TNMP) (Wielinga *et al.*, 2002). Whereas the 6-thioguanine nucleotides are responsible for immunosuppressant activity, 6-methylmercaptopurine nucleotides have been associated with hepatotoxicity at high doses (Gearry *et al.*, 2010). Thiopurine nucleosides have also been shown to be transported by the transporters MRP4 (ABCC4) and MRP5 (ABCC5) (Wielinga *et al.*, 2002). Another example of an unusual conjugate is that of the immunosuppressant macrolide everolimus, which forms a phosphocholine conjugate as a major metabolite (ATG181) in both animals and humans (Zollinger *et al.*, 2008). While phosphocholine esters of endogenous lipids, such as sphingomyelins or phosphatidylcholines, are common, phosphocholine conjugates of xenobiotics are very rare. Previously, only fluorescence-labeled endogenous lipids and an unnatural stereoisomer of dihydroceramide have been shown to form this type of conjugate (Zollinger *et al.*, 2008). The addition of activated phosphocholine is catalyzed by the enzymes cholinephosphotransferase found in the Golgi apparatus, as well as choline/ethanolaminephosphotransferase found in the endoplasmic reticulum and nuclear envelope; however, it is not known whether these enzymes also catalyze the phosphocholine conjugation of everolimus (Zollinger *et al.*, 2008). Furthermore, the tyrosine kinase inhibitor, imatinib, has also been shown to generate a novel ADP⁺ adduct when incubated in vitro with rat liver microsomes and the cofactor NADPH (Ma *et al.*, 2008). This activity has been attributed to the enzyme NAD-glycohydrolase, which has been previously shown to be involved in the ADP⁺ conjugation of many pyridine-containing compounds such as cotinine, nicotinic acid, 3-acetyl pyridine, nicotinic acid hydrazine, 6-aminocotinamide, and nitrosamines, and thiophenopyridine-containing I κ B-kinase β inhibitors (Ma *et al.*, 2008). The conjugating enzyme, NAD-glycohydrolase, functions through the cleavage of the nicotinamide-ribose bond of NADP⁺ which in turn generates an oxocarbenium ion intermediate with subsequent transfer of the ADP-ribosyl group to water, methanol, or pyridine-containing

Figure 6-68. Examples of unusual conjugation reactions.

compounds (Ma *et al.*, 2008). NAD-glycohydrolase is ubiquitously expressed in many organisms, including mammals, and the implications of xenobiotic-ADP⁺ adducts formed by this enzyme are not well understood (Ma *et al.*, 2008).

Phosphorylation

Some drugs are intentionally designed to be phosphorylated by intracellular enzymes. For example, the anti-HIV drug zidovudine (AZT) is converted to a triphosphate nucleoside by enzymes in the salvage pathway (nucleoside kinase, nucleoside monophosphate kinase [NMK], and nucleoside diphosphate kinase [NDK]). However, phosphorylation of xenobiotics is the exception rather than the rule. All conjugation reactions ultimately require ATP, either to activate the xenobiotic for conjugation with GSH or amino acids or to synthesize high-energy cofactors such as UDPGA and PAPS. The process is inefficient in that several ATP molecules (or their equivalent) are used to synthesize each cofactor molecule. The question arises: why is ATP not used directly by conjugating enzymes? In other words, why are xenobiotics

never phosphorylated directly (with the exception of drugs such as zidovudine), which would require less ATP and would achieve the goal of converting xenobiotics to water-soluble conjugates? It is difficult to be certain why this does not occur, but 4 reasons suggest themselves. First, if xenobiotics could be phosphorylated, high intracellular levels of a xenobiotic might consume so much ATP as to jeopardize cell viability, whereas UDPGA and PAPS can be depleted without killing cells. Second, phosphorylation of endogenous substrates, such as glucose, is a mechanism for trapping endogenous substrates inside a cell. This works because the plasma membrane of all cells is a barrier to the passage of polar compounds by virtue of its hydrophobic properties (lipid bilayer) and its general lack of transporters that efflux phosphorylated compounds out of the cell. The same is true for the phosphorylated metabolites of zidovudine and related antiviral drugs; they are retained inside the cell that forms them. A lipid bilayer is also a physical barrier to other water-soluble conjugates, such as glucuronides and sulfonates, but these are transported out of the cell by various transporters. Third, phosphorylation of both small molecules (such as inositol) and proteins (such as membrane-bound

receptors and various transcription factors) plays an important role in intracellular and intranuclear signaling. It is possible that some xenobiotics, if they were phosphorylated, might interfere with these regulatory systems and thereby disrupt cellular homeostasis. Fourth, even if xenobiotics were phosphorylated in the liver and excreted in bile, they would be rapidly hydrolyzed by high levels of alkaline phosphatase lining the surface of enterocytes in the small intestine, which would promote reabsorption of the xenobiotic (by the very process exploited in the design of phosphorylated prodrugs such as fosamprenavir). Whatever the reason, there appears to be strong evolutionary pressure against the conjugation of xenobiotics with phosphoric acid.

INTRODUCTION

Toxicokinetics is the quantitative study of the movement of an exogenous chemical from its entry into the body, through its distribution to organs and tissues via the blood circulation, and to its final disposition by way of biotransformation and excretion. The basic kinetic concepts for the absorption, distribution, metabolism, and excretion of chemicals in the body system initially came from the study of drug actions or pharmacology; hence, this area of study is traditionally referred to as pharmacokinetics. Toxicokinetics represents extension of kinetic principles to the study of toxicology and encompasses applications ranging from the study of adverse drug effects to investigations on how disposition kinetics of exogenous chemicals derived from either natural or environmental sources (generally refer to as xenobiotics) govern their deleterious effects on organisms including humans.

The study of toxicokinetics relies on mathematical description or modeling of the time course of toxicant disposition in the whole organism. The classic approach to describing the kinetics of drugs is to represent the body as a system of one or more compartments, even though the compartments do not have exact correspondence to anatomical structures or physiological processes. These empirical compartmental models are almost always developed to describe the kinetics of toxicants in readily accessible body fluids (mainly blood) or excreta (eg, urine, stool, and breath). This approach is particularly suited for human studies, which typically do not afford organ or tissue data. In such applications, extravascular distribution, which does not require detail elucidation, can be represented simply by lumped compartments. An alternate and newer approach,

physiologically based toxicokinetic modeling attempts to portray the body as an elaborate system of discrete tissue or organ compartments that are interconnected via the circulatory system. Physiologically based models are capable of describing a chemical's movements in body tissues or regions of toxicological interest. It also allows a priori predictions of how changes in specific physiological processes affect the disposition kinetics of the toxicant (eg, changes in respiratory status on pulmonary absorption and exhalation of a volatile compound) and the extrapolation of the kinetic model across animal species to humans.

It should be emphasized that there is no inherent contradiction between the classic and physiological approaches. The choice of modeling approach depends on the application context, the available data, and the intended utility of the resultant model. Classic compartmental model, as will be shown, requires assumptions that limit its application. In comparison, physiological models can predict tissue concentrations; however, it requires much more data input and often the values of the required parameters cannot be estimated accurately or precisely, which introduces uncertainty in its prediction.

We begin with a description of the classic approach to toxicokinetic modeling, which offers an introduction to the basic kinetic concepts for toxicant absorption, distribution, and elimination. This will be followed by a brief review of the physiological approach to toxicokinetic modeling that is intended to illustrate the construction and application of these elaborate models. Finally, we will address the application of toxicokinetic principles to biological monitoring for exposure assessments in industrial and environmental contexts.

Ideally, quantification of xenobiotic concentration at the site of toxic insult or injury would afford the most direct information on exposure–response relationship and dynamics of response over time. Serial sampling of relevant biological tissues following dosing can be cost-prohibitive during in vivo studies in animals and is nearly impossible to perform in human exposure studies. The most accessible and simplest means of gathering information on absorption, distribution, metabolism, and elimination of a compound is to examine the time course of blood or plasma toxicant concentration over time. If one assumes that the concentration of a chemical in blood or plasma is in some describable dynamic equilibrium with its concentrations in tissues, then changes in plasma toxicant concentration should reflect changes in tissue toxicant concentrations and relatively simple kinetic models can adequately describe the behavior of that toxicant in the body system.

Classic toxicokinetic models typically consist of a central compartment representing blood and tissues that the toxicant has ready access and equilibration is achieved almost immediately following its introduction, along with one or more peripheral compartments that represent tissues in slow equilibration with the toxicant in blood (Fig. 7-1). Once introduced into the central compartment, the toxicant distributes between central and peripheral compartments. Elimination of the toxicant, through biotransformation and/or excretion, is usually assumed to occur from the central compartment, which should comprise the rapidly perfused visceral organs capable of eliminating the toxicant (eg, kidneys, lungs, and liver). The obvious advantage of compartmental toxicokinetic models is that they do not require information on tissue physiology or anatomic structure. These models are useful in predicting the toxicant concentrations in blood at different doses or exposure levels, in establishing the time course of accumulation of the toxicant, either in its parent form or as biotransformed products during continuous or episodic exposures, in defining concentration–response (vs dose–response) relationships, and in

Figure 7-1. Compartmental toxicokinetic models. Symbols for 1-compartment model: k_a is the first-order absorption rate constant, and k_{el} is the first-order elimination rate constant. Symbols for 2-compartment model: k_a is the first-order absorption rate constant into the central compartment (1), k_{10} is the first-order elimination rate constant from the central compartment (1), k_{12} and k_{21} are the first-order rate constants for distribution between central (1) and peripheral (2) compartment.

guiding the choice of effective dose and design of dosing regimen in animal toxicity studies (Rowland and Tozer, 2011).

One-Compartment Model

The most straightforward toxicokinetic assessment entails quantification of the blood or more commonly plasma concentrations of a toxicant at several time points after a bolus intravenous (iv) injection.

Often, the data obtained fall on a straight line when they are plotted as the logarithm of plasma concentration versus time; the kinetics of the toxicant is said to conform to a one-compartment model (Fig. 7-2). Mathematically, this means that the decline in plasma concentration over time profile follows a simple exponential pattern as represented by the following mathematical expressions:

$$C = C_0 \cdot e^{-k_{el} \cdot t} \quad (7-1)$$

or its logarithmic transform

$$\text{Log } C = \text{Log } C_0 - \frac{k_{el} \cdot t}{2.303} \quad (7-2)$$

where C is the plasma toxicant concentration at time t after injection, C_0 is the plasma concentration achieved immediately after injection, and k_{el} is the exponential constant or elimination rate constant with dimensions of reciprocal time (eg, minute^{-1} or hour^{-1}). The constant 2.303 in Equation (7-2) is needed to convert natural logarithm into base-10 logarithm. It can be seen from Equation (7-2) that the elimination rate constant can be determined from the slope of the $\log C$ versus time plot (ie, $k_{el} = -2.303 \cdot \text{slope}$).

The elimination rate constant k_{el} represents the overall elimination of the toxicant, which includes biotransformation, exhalation, and/or excretion pathways. When elimination of a toxicant from the body occurs in an exponential fashion, it signifies a first-order process, that is, the rate of elimination at any time is proportional to the amount of toxicant remaining in the body (ie, body load) at that time. This means that following an iv bolus injection, the absolute rate of elimination (eg, milligrams of toxicant eliminated per minute) continually changes over time. Shortly after introduction of the dose, the rate of toxicant elimination will be at the highest. As elimination proceeds and body load of the toxicant is reduced, the elimination rate will decline in step. As a corollary, it also means that at multiple levels of the toxicant dose, the absolute rate of elimination at corresponding times will be proportionately more rapid at the higher doses. This mode of elimination offers an obvious advantage for the organism to deal with increasing exposure to a toxicant. First-order kinetics occur at toxicant concentrations that are not sufficiently high to saturate either metabolic or transport processes.

In view of the nature of first-order kinetics, k_{el} is said to represent a constant fractional rate of elimination. Thus, if the fractional elimination rate is constant, for example, 0.3 hour^{-1} , the percentage of dose or plasma concentration remaining in the body ($C/C_0 \cdot 100$) and the percentage of the dose or concentration eliminated from the body after 1 hour, that is, $1 - (C/C_0 \cdot 100)$, are 74% and 26%, respectively, regardless of the dose administered (Table 7-1). The reason why the amount remaining at 1 hour is slightly more than 70%, or the amount eliminated is less than 30%, is because the amount in the body declined continually over the 1-hour period and thus the actual amount eliminated is less than anticipated based on the starting amount in the body. Again, this illustrates the fact that under first-order kinetics, the actual elimination rate declines with the depletion in body load, but the percentage eliminated over a given period of time is the same regardless of dose, that is, the

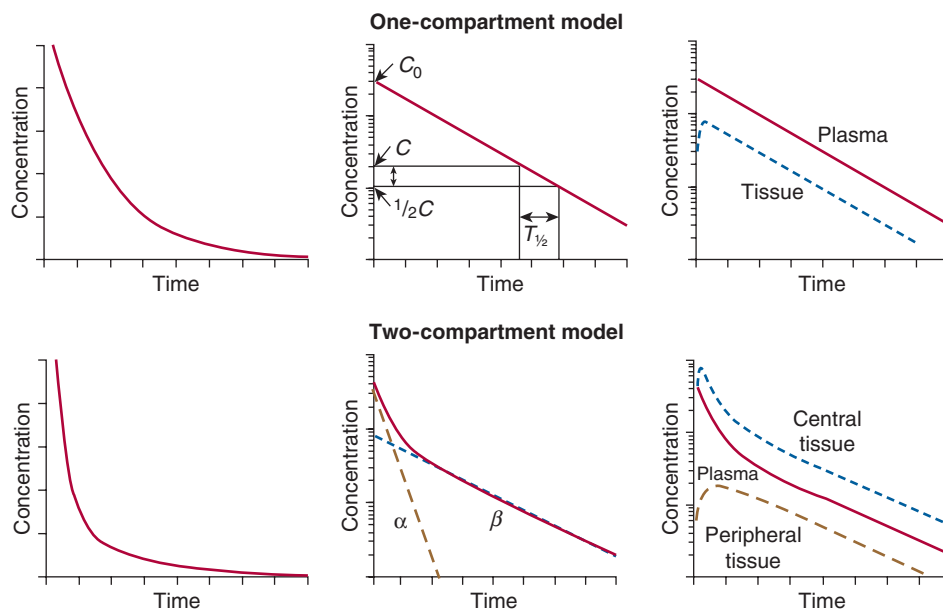

Figure 7-2. Plasma concentration versus time curves of toxicants exhibiting kinetic behavior conforming to a 1-compartment model (top row) and a 2-compartment model (bottom row) following *iv* bolus injection. Left and middle panels show the plots on a rectilinear and semilogarithmic scale, respectively. Right panels illustrate the relationship between tissue (dash lines) and plasma (solid line) concentrations over time. The right panel for the 1-compartment model shows the concentration–time profile for a typical tissue with a higher concentration than plasma. Note that tissue concentration can be higher, nearly the same, or lower than plasma concentration. Tissue concentration peaks almost immediately, and thereafter declines in parallel with plasma concentration. The right panel for the 2-compartment model shows concentration–time profiles for typical tissues associated with the central (1) and peripheral (2) compartments as represented by short and long dash lines, respectively. For tissues associated with the central compartment, their concentrations decline in parallel with plasma. For tissues associated with peripheral compartment, toxicant concentration rises, while plasma concentration declines rapidly during the initial phase; it then reaches a peak and eventually declines in parallel with plasma in the terminal phase. Elimination rate constant k_{el} for 1-compartment model and the terminal exponential rate constant β are determined from the slope of the log–linear concentration versus time curve. Half-life ($T_{1/2}$) is the time required for plasma toxicant concentration to decrease by one-half. C_0 is the concentration of a toxicant for a 1-compartment model at $t = 0$ determined by extrapolating the log–linear concentration–time curve to the *Y*-axis.

fractional rate of elimination of the toxicant remains constant over time after *iv* injection or any acute exposure. Because a constant percentage of toxicant present in the body is eliminated over a given time period regardless of dose or the starting concentration, it is more intuitive and convenient to refer to an elimination half-life ($T_{1/2}$), that is, the time it takes for the original blood or plasma concentration to fall by 50% or to eliminate 50% of the original body load. By substituting $C/C_0 = 0.5$ into Equation (7-1), we obtain the following relationship between $T_{1/2}$ and k_{el} :

$$T_{1/2} = \frac{0.693}{k_{el}} \quad (7-3)$$

Table 7-1

Elimination of a Toxicant That Follows First-Order Kinetics ($k_{el} = 0.3 \text{ h}^{-1}$) by 1 Hour After *iv* Administration at Four Different Dose Levels

DOSE (mg)	TOXICANT REMAINING (mg)	TOXICANT ELIMINATED (mg)	TOXICANT ELIMINATED (% of dose)
10	7.4	2.6	26
30	22	8	26
90	67	23	26
250	185	65	26

where 0.693 is the natural logarithm of 2. Simple calculations reveals that it would take about 4 half-lives for >90% (exactly 93.8%) of the dose to be eliminated, and about 7 half-lives for >99% (exactly 99.2%) elimination. Thus, given the elimination $T_{1/2}$ of a toxicant, the length of time it takes for near-complete wash-out of a toxicant after discontinuation of its exposure can easily be estimated. As will be seen in next section, the concept of $T_{1/2}$ is also applicable to toxicants that exhibit multiexponential kinetics.

We can infer from the monoexponential decline of blood or plasma concentration that the toxicant equilibrates very rapidly between blood and the various tissues relative to the rate of elimination, such that extravascular equilibration is achieved nearly instantaneously and maintained thereafter. Depiction of the body system by a one-compartment model does not mean that the concentration of the toxicant is the same throughout the body, but it does assume that the changes that occur in the plasma concentration reflect proportional changes in tissue toxicant concentrations (Fig. 7-2 upper, right panel). In other words, toxicant concentrations in tissues are expected to decline with the same elimination rate constant or $T_{1/2}$ as in plasma; tissue and plasma concentrations should decline in parallel.

Two-Compartment Model

After rapid *iv* administration of some toxicants, the semilogarithmic plot of plasma concentration versus time does not yield a straight line but a curve that implies more than one dispositional phase (Fig. 7-2). In these instances, it takes some time for the toxicant to be taken up into certain tissue groupings, and to then

Table 7-2

Prediction of Equilibration Half-Times for Tissues in the Groupings of Highly Perfused Visceral Tissues, Poorly Perfused Lean Tissues, and Adipose Tissues for a Lipid-Soluble, Organic Toxicant With Assumed Typical Tissue-to-Blood Partitioning Ratios (P)*

GROUPING	TISSUE	PERFUSION (L/min) [†]	VOLUME (L) [†]	EQUILIBRATION $T_{1/2}$ (Min) [‡]
Highly perfused visceral tissues, $P = 1$	Heart	0.20	0.28	0.97
	Lungs	5.0	1.1	0.15
	Liver, Gut	1.4	1.6	0.79
	Kidneys	1.1	0.35	0.22
	Brain	0.70	1.4	1.4
Poorly perfused tissues, $P = 0.5$	Muscle (resting)	0.75	30	14
	Skin (cool weather)	0.30	7.7	9.0
Adipose tissue, $P = 5$	—	0.20	14	243

*Adapted from Rowland and Tozer (2011).

[†]Data taken from the compilation of Rowland and Tozer (2011), Table 4-4 on p. 88.

[‡]Equilibration half-time is the predicted time it takes to achieve 50% of the eventual equilibrated concentration in a tissue when arterial toxicant concentration is held constant and assuming that distribution is perfusion rate-limited. It is calculated by $(0.693 \cdot V \cdot P)/Q$, where Q is the blood perfusion rate of the tissue, V is the tissue volume, and P is the tissue-to-blood partition ratio.

Note that the equilibration half-times for the highly perfused visceral tissues are predicted to be very short, <2 minutes. The equilibration half-times for poorly perfused lean tissues are estimated to be around 10 to 20 minutes. The equilibration half-time predicted for fat is the order of at least several hours. This tissue grouping in equilibration kinetics gives rise to multiphasic toxicokinetics that are describable by 2- or 3-compartment models.

reach an equilibration with the concentration in plasma; hence, a multicompartamental model is needed for the description of its kinetics in the body (Fig. 7-1). The concept of tissue groupings with distinct uptake and equilibration rates of toxicant becomes apparent when we consider the factors that govern the uptake of a lipid-soluble, organic toxicant. Table 7-2 presents data on the volume and blood perfusion rate of various organs and tissues in a standard size human. From these data and assuming reasonable partitioning ratios of a typical lipid-soluble, organic compound in the various tissue types, we can estimate the uptake equilibration half times of the toxicant in each organ or tissue region during constant, continuous exposure. The results suggest that the tissues can be grouped into rapid-equilibrating visceral organs, moderately slow-equilibrating lean body tissues (mainly skeletal muscle), and very slow-equilibrating body fat; these groupings give rise to three distinct uptake phases, that is, half times of <2 minutes for the rapid-equilibrating tissues, several tens of minutes for the moderately slow-equilibrating lean body tissues, and hours for the very slow-equilibrating body fat. By inference, three distinct phases of washout should also be evident following a brief exposure to the toxicant, such as after a bolus iv injection. The relative prominence of these distributional phases will vary depending on the average lipid solubility of the toxicant in each tissue grouping and any other sequestration and export mechanisms of a toxicant in particular tissues (eg, tight binding to tissue proteins, active influx into or efflux out of the tissue cell types), as well as the competing influence of elimination from the visceral organs. For example, very rapid metabolism or excretion at the visceral organs would limit distribution into the slow or very slow tissue groupings. Also, there are times when equilibration rates of a toxicant into visceral organs overlaps with lean body tissues, such that the distribution kinetics of a toxicant into these two tissue groupings become indistinct with respect to the exponential decline of plasma concentration, in which case two instead of three tissue groupings may be observed. The concept of tissue groupings with respect to uptake or washout kinetics serves

to justify the seemingly simplistic, yet pragmatic, mathematical description of extravascular distribution by the classic two- or three-compartment models.

Plasma concentration–time profile of a toxicant that exhibits multicompartamental kinetics can be characterized by multiexponential equations. For example, a two-compartment model can be represented by the following biexponential equation:

$$C = A \cdot e^{-\alpha t} + B \cdot e^{-\beta t} \quad (7-4)$$

where A and B are coefficients in units of toxicant concentration, and α and β are the respective exponential constants for the initial and terminal phases in units of reciprocal time. The initial (α) phase is often referred to as the distribution phase, and terminal (β) phase as the postdistribution or elimination phase. The lower, middle panel of Fig. 7-2 shows a graphical resolution of the two exponential phases from the plasma concentration–time curve. It should be noted that the α constant is the slope of the residual log-linear plot and not the initial slope of the decline in the observed plasma toxicant concentration, that is, the initial rate of decline in plasma concentration approximates, but is not exactly equal, the α rate constant in Equation (7-4).

It should be noted that distribution into and out of the tissues and elimination of the toxicant are ongoing at all times, that is, elimination does occur during the “distribution” phase, and distribution between compartments is still ongoing during the “elimination” phase. As illustrated in Fig. 7-3, the dynamics of a multicompartamental system is such that the governing factor, that is, be it intercompartmental distribution or elimination, for each of the phases depends on the relative magnitude of the rate constants for intercompartmental exchange and the elimination process. In the usual case, that of rapid distribution and relatively slow elimination (left panel of Fig. 7-3), the initial rapid phase indeed reflects extravascular distribution, and the later, slow phase reflects elimination after a dynamic equilibration between tissue and blood is attained. There are cases where distribution into some tissue group is much slower than elimination. Then, the initial phase could largely reflect

Figure 7-3. Effects of interplay between kinetics of distribution and elimination processes on time course of exchange between body compartments and removal from the body for toxicants whose disposition conforms to a 2-compartment model. Left panel depicts the more common scenario of rapid distribution between compartments relative to elimination, in which case elimination from the body occurs largely during the terminal phase when a dynamic equilibration between the central and peripheral compartment has been reached. Accordingly, half-life of the terminal phase is an appropriate measure of elimination. Right panel depicts the scenario of very slow distribution relative to elimination, in which case a substantial (>90% of dose) loss of toxicant occurs during the initial phase. The terminal phase reflects the slow redistribution of the toxicant sequestered in the peripheral site to the central site where it can be eliminated (ie, washout is rate-limited by redistribution). Under this scenario, the initial phase reflects elimination kinetics, whereas the terminal phase reflects tissue distribution kinetics. (Adapted from Tozer and Rowland, 2006.)

elimination, and the later phase is controlled by the slow redistribution of the toxicant from the tissues associated with the peripheral compartment to the central compartment, where it is eliminated (ie, washout in the terminal phase is rate-limited by redistribution from the peripheral compartment). The aminoglycoside antibiotic gentamicin is a case in point (Schentag and Jusko, 1977). Following an iv injection of gentamicin in patients with normal renal function, serum gentamicin concentration exhibits biphasic kinetics. Serum concentration of gentamicin initially falls very quickly with a half-life of around 2 hours reflecting rapid excretion by the kidneys; a slow terminal phase does not emerge until serum concentration has fallen to less than 10% of initial concentration. The terminal half-life of serum gentamicin is in the range of 4 to 7 days. This protracted terminal half-life reflects the slow turnover of gentamicin sequestered in the kidneys. In fact, repeated administration of gentamicin leads to accumulation of gentamicin in the kidneys, which is a risk factor for its nephrotoxicity. Because of the interplay of distribution and elimination kinetics, it has been recommended that multiphasic disposition should be simply described as consisting of early and late or rapid and slow phases; mechanistic labels of distribution and elimination should be applied with some caution. Lastly, the initial phase may last for only a few minutes or for hours. Whether multiphasic kinetics becomes apparent depends to some extent on how often and when the early blood samples are obtained, and on the relative difference in the exponential rate constants between the early and later phases. If the early phase of decline in toxicant concentration is considerably more rapid than the later phase or phases, the timing of blood sampling becomes critical in the ability to resolving two or more phases of washout.

Sometimes three or even 4 exponential terms are needed to fit a curve to the plot of $\log C$ versus time. Such compounds are viewed as displaying characteristics of three- or four-compartment open models. The principles underlying such models are the same as those applied to the two-compartment open model, but the mathematics is more complex and beyond the scope of this chapter.

Apparent Volume of Distribution

For a one-compartment model, a toxicant is assumed to equilibrate between plasma and tissues immediately following its entry into the systemic circulation. Thus, a consistent relationship should exist between plasma concentration and the amount of toxicant in each tissue and, by extension, to the entire amount in the body or body burden. The apparent volume of distribution (V_d) is defined as the proportionality constant that relates the total amount of the toxicant in the body to its concentration in plasma, and typically has units of liters or liters per kilogram of body weight (Rowland and Tozer, 2011). V_d is the apparent fluid space into which an amount of toxicant is distributed in the body to result in a given plasma concentration. As an illustration, envision the body as a tank containing an unknown volume (L) of well-mixed water. If a known amount (mg) of dye is placed into the water, the volume of that water can be calculated indirectly by determining the dye concentration (mg/L) that resulted after the dye has fully dispersed, that is, by dividing the amount of dye added to the tank by the resultant concentration of the dye in water. Analogously, the apparent volume of distribution of a toxicant in the body is determined after iv bolus administration, and is mathematically defined as the quotient of the amount of toxicant in the body and its plasma concentration. V_d is calculated as

$$V_d = \frac{Dose_{iv}}{\beta \cdot AUC_0^\infty} \quad (7-5)$$

where $Dose_{iv}$ is the iv dose or known amount of toxicant in the body at time zero, β is the elimination rate constant, and AUC_0^∞ is the area under the toxicant concentration versus time curve from time zero to infinity. AUC_0^∞ is estimated by numerical methods, the most common one being the trapezoidal rule (Gibaldi and Perrier, 1982). The product, $\beta \cdot AUC_0^\infty$, in unit of concentration, is the theoretical concentration of toxicant in plasma if dynamic equilibration were achievable immediately after introduction of the toxicant into

372 the systemic circulation. For a 1-compartment model, immediate equilibration of the toxicant between plasma and tissues after an acute exposure does hold true, in which case V_d can be calculated by a simpler and more intuitive equation

$$V_d = \frac{\text{Dose}_{iv}}{C_0} \quad (7-6)$$

where C_0 is the concentration of toxicant in plasma at time zero. C_0 is determined by extrapolating the plasma disappearance curve after iv injection to the zero time point (Fig. 7-2, upper, middle panel).

For the more complex multicompartmental models, V_d is calculated according to Equation (7-5) that involves the computation of area under the toxicant concentration-time curve. Moreover, the concept of an overall apparent volume of distribution is strictly applicable to the terminal exponential phase when equilibration of the toxicant between plasma and all tissue sites are attained. This has led some investigators to refer to the apparent volumes of distribution calculated by Equation (7-5) as V_β (for a two-compartment model) or V_z (for a general multicompartmental model); the subscript designation refers to the terminal exponential phase (Gibaldi and Perrier, 1982). It should also be noted that when Equation (7-6) is applied to the situation of a multicompartmental model, the resultant volume is the apparent volume of the central compartment, often times referred to as V_c . By definition, V_c is the proportionality constant that relates the total amount of the toxicant in the central compartment to its concentration in plasma. It has limited utility, for example, it can be used to calculate an iv dose of the toxicant to target an initial plasma concentration.

V_d is appropriately called the *apparent* volume of distribution because it does not correspond to any real anatomical volumes. The magnitude of the V_d term is toxicant-specific and represents the extent of distribution of toxicant out of plasma and into extravascular sites (Table 7-3). Equation (7-7) provides a more intuitive interpretation of an apparent volume of distribution:

$$V_d = V_p + \sum P_{ti} \cdot V_{ti} \quad (7-7)$$

where V_p is the plasma volume and the Σ represents the summation of the apparent volume of each tissue region (t,i) as represented by the product of P_{ti} (ie, partition ratio or tissue-to-plasma concentration ratio at dynamic equilibrium) and V_{ti} (ie, anatomical volume of tissue). At one extreme, a toxicant that predominantly remains in the vasculature will have a low V_d that approximates the volume of blood or plasma, that is, the minimum V_d for any toxicant is the plasma volume. For toxicants that distribute extensively into extravascular tissues, V_d exceeds physiological fluid spaces, such as plasma or blood volume, interstitial fluid, or extracellular fluid. A toxicant that is highly sequestered in tissues (ie, high P_{ti}) can have a volume of distribution larger than average body size (>1 L/kg). The mechanisms of tissue sequestration include partitioning of a toxicant into tissue fat, high-affinity binding to tissue proteins, trapping in specialized organelles (eg, pH trapping of amine compounds in acidic lysosomes), and concentrative uptake by active transporters. In fact, the equation below is an alternate form of Equation (7-7), which features the interplay of binding to plasma and tissue proteins in determining the partitioning of a toxicant in that only free or unbound drug can freely diffuse across membrane and cellular barriers.

$$V_d = V_p + \sum \left(\frac{f_{up}}{f_{ut,i}} \right) \cdot V_{ti} \quad (7-8)$$

Table 7-3

Volume of Distribution (V_d) and Unbound or Free Fraction in Plasma (f_{up}) for Several Drugs That Are of Clinical Toxicological Interest

CHEMICAL	V_d (L/kg)	f_{up}
Chloroquine	~200	~0.45
Nortriptyline	18	0.080
Oxycodone	2.0	0.55
Body size = 1.0		
Acetaminophen	0.95	<0.20
Total body water = 0.60		
Phenytoin	0.64	0.11
Extracellular fluid = 0.27		
Warfarin	0.14	0.005
Epoetin alfa	0.05	–
Plasma volume = 0.045		
<i>Volumes of body fluid compartments in healthy human adults are included for comparison.</i>		
<i>Data from Thummel et al. (2006).</i>		

where f_{up} is the unbound fraction of toxicant in plasma and $f_{ut,i}$ is the effective unbound fraction in a tissue region. Here, P_{ti} is governed by the ratio $f_{up} / f_{ut,i}$. Thus, a toxicant that has high affinity for plasma proteins (eg, albumin and/or α_1 -acid glycoprotein) relative to tissue proteins has a restricted distribution volume; for example, the anticoagulant warfarin with a plasma-bound fraction of 0.995 or an f_{up} of 0.005 (Table 7-3). On the contrary, a toxicant that has a high affinity for tissue proteins and lesser affinity for plasma proteins can have a very high V_d . For example, the tricyclic antidepressant nortriptyline has a good affinity for plasma proteins with a bound fraction of 0.92 or an f_{up} of 0.08; however, binding of nortriptyline to tissues constituents is so much higher such that it has a V_d of 18 times the body weight in adult humans.

In addition to its value as a parameter to indicate the extent of extravascular distribution of a toxicant, V_d also has practical utility. Once the V_d for a toxicant is known, it can be used to estimate the amount of toxicant remaining in the body at any time when the plasma concentration at that time is known, that is,

$$X_B = V_d \cdot C \quad (7-9)$$

where X_B is the amount of toxicant in the body or body burden, and C is the plasma concentration at a time after equilibration between tissue and plasma had been achieved.

Clearance

Toxicants are cleared from the body via various routes, for example, excretion by the kidneys into urine or via bile into the intestine ending in feces, biotransformation by the liver, or exhalation by the lungs. Clearance is an important toxicokinetic parameter that relates the rate of toxicant elimination from the whole body in relation to plasma concentration (Wilkinson, 1987). Although terminal $T_{1/2}$ is reflective of the rate of removal of a toxicant from plasma or blood, as was explained earlier, it is also subject to the influence of distributional processes, especially for toxicants exhibiting multicompartmental kinetics.

Clearance, on the contrary, is a parameter that solely represents the rate of toxicant elimination; it is not influenced by extravascular distribution.

A formal definition of total body clearance is the ratio of overall elimination rate of a toxicant divided by plasma concentration at any time after an acute exposure or during repetitive or continuous exposure (ie, elimination rate/ C); in effect, clearance expresses the overall efficiency of the elimination mechanisms. Because this measure of elimination efficiency is in reference to blood or plasma toxicant concentration, it is also named blood or plasma clearance. High values of clearance indicate efficient and generally rapid removal, whereas low clearance values indicate slow and less efficient removal of a toxicant from the body. By definition, clearance has the units of flow (eg, mL/min or L/h). In the classic compartmental context, clearance is portrayed as the apparent volume containing the toxicant that is cleared per unit of time. After iv bolus administration, total body clearance (Cl) is calculated by

$$Cl = \frac{\text{Dose}_{iv}}{AUC_0^\infty} \quad (7-10)$$

Clearance can also be calculated if the volume of distribution and elimination rate constants are known within the context of a compartmental model; that is, $Cl = V_d \cdot k_{el}$ for a 1-compartment model and $Cl = V_\beta \cdot \beta$ for a 2-compartment model. It should be noted that the preceding relationship is a mathematical derivation and does not imply that clearance is dependent on the distribution volume (see later section for further commenting). A clearance of 100 mL/min can be visualized as having 100 mL of blood or plasma completely cleared of toxicant in each minute during circulation.

The biological significance of total body clearance is better appreciated when it is recognized that it is the sum of clearances by individual eliminating organs (ie, organ clearances):

$$Cl = Cl_r + Cl_h + Cl_p + \dots \quad (7-11)$$

where Cl_r depicts renal, Cl_h hepatic, and Cl_p pulmonary clearance. Each organ clearance is in turn determined by blood perfusion flow through the organ (i) and the fraction of toxicant in the arterial inflow that is irreversibly removed, that is, the extraction fraction (E_i). Various organ clearance models have been developed to provide quantitative description of clearance that is related to blood perfusion flow (Q_i), free fraction in blood (f_{ub}), and intrinsic clearance ($Cl_{int,i}$) (Wilkinson, 1987). For example, for hepatic clearance (Cl_h), if the delivery of the toxicant to its intracellular site of removal is rate-limited by liver blood flow (Q_h) and the toxicant is assumed to have equal, ready access to all the hepatocytes within the liver (ie, the so-called well-stirred model):

$$Cl_h = Q_h \cdot E_h = \frac{Q_h \cdot f_{ub} \cdot Cl_{int,h}}{f_{ub} \cdot Cl_{int,h} + Q_h} \quad (7-12)$$

where $Cl_{int,h}$ is the hepatic intrinsic clearance that embodies a combination of factors that determine the access of the toxicant to the enzymatic sites (eg, plasma protein binding and sinusoidal membrane transport) and the biochemical efficiency of the metabolizing enzymes (eg, V_{max}/K_M for an enzyme obeying Michaelis kinetics). $Cl_{int,h}$ would also embody canalicular transport activity if the toxicant is subject to biliary excretion. Equation (7-12) dictates that hepatic clearance of a toxicant from the blood is bounded by either liver blood flow or intrinsic clearance (ie, $f_{ub} \cdot Cl_{int,h}$). Note that when $f_{ub} \cdot Cl_{int,h}$ is very much higher than Q_h , E_h approaches

unity (ie, near-complete extraction during each passage of toxicant through the hepatic sinusoid or high extraction) and Cl_h approaches Q_h . Put in another way, hepatic clearance cannot exceed the hepatic blood flow rate even if the intrinsic rate of metabolism in the liver is more rapid than the rate of hepatic blood flow because the rate of overall hepatic clearance is limited by the delivery of the toxicant to the metabolic enzymes in the liver via the blood. At the other extreme, when $f_{ub} \cdot Cl_{int,h}$ is very much lower than Q_h , E_h becomes quite small (ie, low extraction) and Cl_h nearly equals $f_{ub} \cdot Cl_{int,h}$. In this instance, the intrinsic clearance is relatively inefficient; hence, alteration in liver blood flow would have little, if any, influence on liver clearance of the toxicant. Thus, the concept of clearance is grounded in the physiological and biochemical mechanisms of an eliminating organ.

Relationship of Elimination Half-Life to Clearance and Volume

Elimination half-life ($T_{1/2}$) is probably the most easily understood toxicokinetic concept and is an important parameter as it measures the persistence of a toxicant following discontinuation of exposure. As will be seen in a later section, elimination half-life also governs the rate of accumulation of a toxicant in the body during continuous or repetitive exposure. Elimination half-life is dependent on both volume of distribution and clearance. $T_{1/2}$ can be calculated from V_d and Cl :

$$T_{1/2} = \frac{0.693 \cdot V_d}{Cl} \quad (7-13)$$

The above relationship among $T_{1/2}$, V_d , and Cl is another illustration that care should be exercised in interpretation of data when relying upon $T_{1/2}$ as the sole representation of elimination of a chemical in toxicokinetic studies, since $T_{1/2}$ is influenced by both the volume of distribution for the toxicant and the rate by which the toxicant is cleared from the blood. For a fixed V_d , $T_{1/2}$ decreases as Cl increases because the chemical is being removed from this fixed volume faster as clearance increases (Fig. 7-4). Conversely, as V_d increases, $T_{1/2}$ increases for a fixed Cl since the volume of fluid that must be cleared of chemical increases but the efficiency of clearance does not.

Figure 7-4. The dependence of $T_{1/2}$ on V_d and Cl . Consider the hypothetical case of a toxicant that is eliminated entirely by renal excretion. Renal Cl values of 60, 130, and 650 mL/min represent partial reabsorption, glomerular filtration, and tubular secretion, respectively. Values for V_d of 3, 18, and 40 L represent approximate volumes of plasma water, extracellular fluid and total body water, respectively, for an average-sized person. Note that $T_{1/2}$ depends on both Cl and V_d .

For most chemicals in toxicology, exposure occurs mostly via extravascular routes (eg, inhalation, dermal, or oral), and absorption into the systemic circulation is often incomplete. The extent of absorption of a toxicant can be experimentally determined by comparing the plasma toxicant concentration after iv and extravascular dosing. Because iv dosing assures full (100%) delivery of the dose into the systemic circulation, the *AUC* ratio should equal the fraction of extravascular dose absorbed and reaches the systemic circulation in its intact form, and is called *bioavailability* (*F*). In acute toxicokinetic studies, bioavailability can be determined by using different iv and non-iv doses according to the following equation, provided that the toxicant does not display dose-dependent or saturable kinetics.

$$F = \frac{(AUC_{\text{non-iv}} / \text{Dose}_{\text{non-iv}})}{(AUC_{\text{iv}} / \text{Dose}_{\text{iv}})} \quad (7-14)$$

where $AUC_{\text{non-iv}}$, AUC_{iv} , $\text{Dose}_{\text{non-iv}}$, and Dose_{iv} are the respective area under the plasma concentration versus time curves and doses for non-iv and iv administration. Bioavailabilities for various chemicals range in value between 0 and 1. Complete availability of chemical to the systemic circulation is demonstrated by $F = 1$. When $F < 1$, less than 100% of the dose is able to reach the systemic circulation. Because the concept of bioavailability is judged by how much of the dose reaches the systemic circulation, it is often referred to as systemic availability. Systemic availability is determined by how well a toxicant is absorbed from its site of application and any intervening processes that could remove or inactivate the toxicant between its point of entry and the systemic circulation. Specifically, systemic availability of an orally administered toxicant is governed by its absorption at the gastrointestinal barrier, metabolism within the intestinal mucosa, and metabolism and biliary excretion during its first transit through the liver. Metabolic inactivation and excretion of the toxicant at the intestinal mucosa and the liver prior to its entry into the systemic circulation is called presystemic extraction or first-pass effect. The following equation accounts for the action of absorption and sequential first-pass extraction at the intestinal mucosa and the liver as determinants of the bioavailability of a toxicant taken orally:

$$F = f_g \cdot (1 - E_m) \cdot (1 - E_h) \quad (7-15)$$

where f_g is the fraction of the applied dose that is released and absorbed across the mucosal barrier along the entire length of the gut, E_m is the extent of loss due to metabolism within the gastrointestinal mucosa, and E_h is the loss due to metabolism or biliary excretion during first-pass through the liver. Note that E_h in this equation is same as the hepatic extraction E_h defined in Equation (7-12), which refers to hepatic extraction of a toxicant during recirculation. This means that low oral bioavailability of a chemical can be attributed to multiple factors. The chemical may be absorbed to a limited extent because of low aqueous solubility preventing its effective dissolution in the gastrointestinal fluid or low permeability across the brush-border membrane of the intestinal mucosa. Extensive degradation by metabolic enzymes residing at the intestinal mucosa and the liver may also minimize entry of the chemical in its intact form into the systemic circulation.

The rate of absorption of a toxicant via an extravascular route of entry is another critical determinant of outcome, particularly in acute exposure situations. As shown in Fig. 7-5, slowing the absorption rate of a toxicant, while maintaining the same extent of absorption or bioavailability, leads to a delay in time to peak plasma

Figure 7-5. Influence of absorption rate on the time to peak (T_p) and maximum plasma concentration (C_{max}) of a toxicant that exhibit 1-compartment kinetics. The left panel illustrates the change in plasma concentration–time curves as the first-order absorption rate constant (k_a) decreases, while keeping the extent of absorption or bioavailability (F), hence the *AUC*, constant. The right panel displays the same curves in a semilogarithmic plot. Time to peak plasma concentration shows a progressive delay as k_a decreases, along with a decrease in C_{max} . In case 1 and 2, the terminal decline in plasma concentration is governed by elimination half-life; hence, the parallel decline in the semilogarithmic plot. In case 3 where $k_a \ll k_{el}$, the absorption becomes so slow that decline in plasma concentration in the terminal phase reflects the absorption half-life, that is, washout of toxicant is rate-limited by absorption. Accordingly, the terminal decline is slower than in case 1 and 2.

concentration (T_p) and a decrease in the maximum concentration (C_{max}) (compare case 2 to case 1). The converse is true; accelerating absorption shortens T_p and increases C_{max} . The dependence of T_p and C_{max} on absorption rate has obvious implication in the speed of onset and maximum toxic effects following exposure to a chemical. Case 3 in Fig. 7-5 illustrates the peculiar situation when the absorption rate is so much slower than the elimination rate (eg, $k_a \ll k_{el}$ for a one-compartment model). The terminal rate of decline in plasma concentration reflects the absorption rate constant, instead of the elimination rate constant; that is, the washout of toxicant is rate-limited by slow absorption until the applied dose is completely absorbed or removed, beyond which time the toxicant remaining in the body will be cleared according the elimination rate-constant. This means that continual absorption of a chemical can affect the persistence of toxic effect following an acute exposure, and that it is important to institute decontamination procedure quickly after overdose or accidental exposure to a toxicant. This is especially a consideration in occupational exposure via dermal absorption following skin contact with permeable industrial chemicals.

Metabolite Kinetics

The toxicity of a chemical is in some cases attributed to its biotransformation product(s). Hence, the formation and subsequent disposition kinetics of a toxic metabolite is at times of interest. In biological monitoring, urinary excretion of a signature metabolite often serves as a surrogate measure of exposure to the parent compound (see later section). As expected, the plasma concentration of a metabolite rises as the parent drug is transformed into the metabolite. Once formed, the metabolite is subject to further metabolism to a nontoxic byproduct or undergoes excretion via the kidneys or bile; hence at some point in time, the plasma metabolite concentration peaks and falls thereafter. Fig. 7-6 illustrates the plasma concentration–time course of a primary metabolite in relation to its parent compound under contrasting scenarios. The left panel shows the case when the elimination rate constant of the metabolite is much greater than the overall elimination rate constant of the parent compound (ie, $k_m \gg k_p$). The terminal decline of the metabolite parallels that of the parent compound; the metabolite is cleared as quickly as it is formed or its washout is rate-limited by

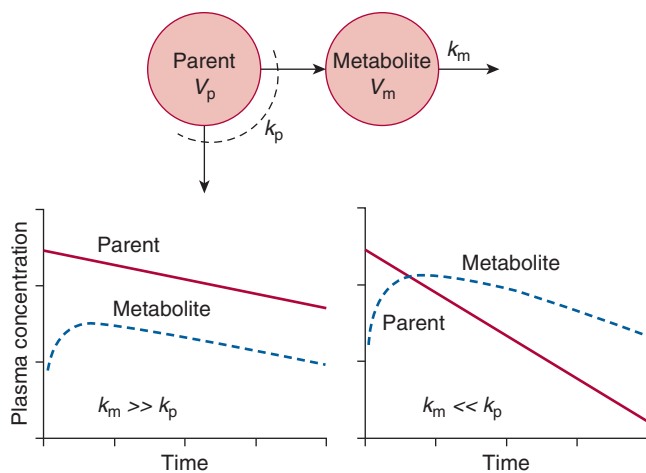

Figure 7-6. Plasma concentration–time course of a primary metabolite and its parent compound under contrasting scenarios: when elimination of the metabolite is much more rapid than its formation ($k_m \gg k_p$, lower left panel) and when elimination of the metabolite is much slower than its formation ($k_m \ll k_p$, lower right panel). Semilogarithmic plots are shown to compare the slope of the terminal decline of parent compound and its metabolite. The top panel shows the model for conversion of the parent compound to a single metabolite. Note that the elimination rate constant for the parent compound (k_p) includes both the rate constants for metabolism and extra-metabolic routes of elimination. k_m is the elimination rate constant for the derived metabolite. When $k_m \gg k_p$, the terminal decline of the metabolite parallels that of the parent compound, that is, metabolite washout is rate-limited by its formation. When $k_m \ll k_p$, the terminal decline of metabolite concentration is much slower than that of parent compound, that is, metabolite washout is rate-limited by its elimination.

conversion from the parent compound. The right panel shows the opposite case when the elimination rate constant of the metabolite is much lower than the overall elimination rate constant of the parent compound (ie, $k_m \ll k_p$). The slower terminal decline of the metabolite compared to the parent compound simply reflects a longer elimination half-life of the metabolite. It should also be noted that the AUC_0^∞ of the metabolite relative to the parent compound is dependent on the partial clearance of the parent drug to the metabolite and clearance of the derived metabolite. A biologically active metabolite assumes toxicological significance when it is the major metabolic product and is cleared much less efficiently than the parent compound.

Saturation Toxicokinetics

As already mentioned, the distribution and elimination of most chemicals occurs by first-order processes. Under first-order elimination kinetics, the elimination rate constant, apparent volume of distribution, clearance, and half-life are expected not to change with increasing or decreasing dose (ie, dose independent). As a result, a semilogarithmic display of plasma concentration versus time over a range of doses shows a set of parallel plots. Furthermore, plasma concentration at a given time or the AUC_0^∞ is strictly proportional to dose; for example, a 2-fold change in dose results in an exact 2-fold change in plasma concentration at a given time after dosing or AUC_0^∞ . However, for some toxicants, as the dose of a toxicant increases, its volume of distribution and/or clearance may change, as shown in Fig. 7-7. This is generally referred to as nonlinear or dose-dependent kinetics. Biotransformation, active transport processes, and protein binding have finite capacities and can be saturated. For instance, most metabolic enzymes operate in accordance to Michaelis–Menten kinetics (Gibaldi and Perrier,

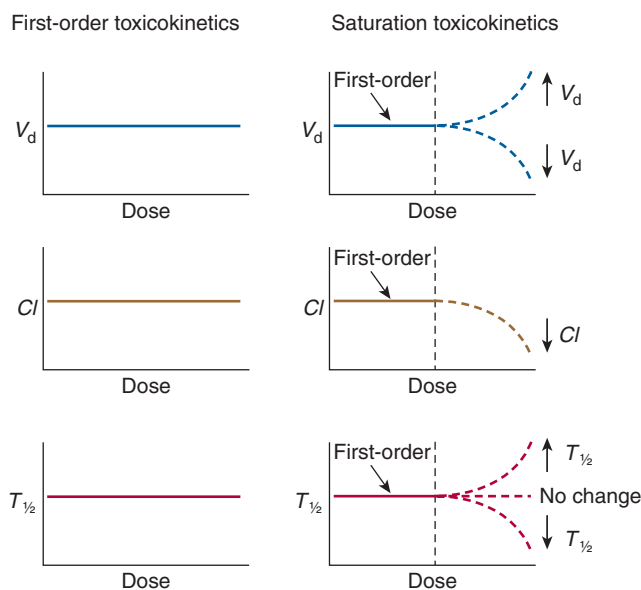

Figure 7-7. Changes in V_d , Cl , and $T_{1/2}$ following first-order toxicokinetics (left panels) and following saturable toxicokinetics (right panels). Vertical dashed lines in the right panels represent point of departure from first-order to saturation toxicokinetics. Pharmacokinetic parameters for toxicants that follow first-order toxicokinetics are independent of dose. When plasma protein binding or elimination mechanisms are saturated with increasing dose, pharmacokinetic parameter estimates become dose-dependent. V_d may increase, for example, when protein binding is saturated, allowing more free toxicant to distribute into extravascular sites. Conversely, V_d may decrease with increasing dose if tissue protein binding saturates. Then, toxicant may redistribute more freely back into plasma. When toxicant concentrations exceed the capacity for biotransformation by metabolic enzymes, overall clearance of the toxicant decreases. These changes may or may not have effects on $T_{1/2}$ depending upon the magnitude and direction of changes in both V_d and Cl .

1982). As the dose is escalated and concentration of a toxicant at the site of metabolism approaches or exceeds the K_M (substrate concentration at one-half V_{max} , the maximum metabolic capacity), the increase in rate of metabolism becomes less than proportional to the dose and eventually approaches a maximum at exceedingly high doses. The transition from first-order to saturation kinetics is important in toxicology because it can lead to prolonged persistence of a compound in the body after an acute exposure and excessive accumulation during repeated exposures. Some of the salient characteristics of nonlinear kinetics include the following: (1) the decline in the concentrations of the chemical in the body is not exponential; (2) AUC_0^∞ is not proportional to the dose; (3) V_d , Cl , k_{el} (or β), or $T_{1/2}$ change with increasing dose; (4) the composition of excretory products changes quantitatively or qualitatively with the dose; and (5) dose–response curves show an abruptly steeper change in response to an increasing dose, starting at the dose at which saturation effects become evident.

Inhaled methanol provides an example of a chemical whose metabolic clearance changes from first-order kinetics at low level exposures to zero-order kinetics at near toxic levels (Burbacher *et al.*, 2004). Fig. 7-8 shows predicted blood methanol concentration–time profiles in female monkeys followed a 2-hour controlled exposure in an inhalation chamber at 2 levels of methanol vapor, 1200 and 4800 ppm. Blood methanol kinetics at 1200 ppm exposure follows typical first-order kinetics. At 4800 ppm, methanol metabolism is fully saturated, such that the initial decline in blood methanol following the 2-hour exposure occurs at a constant rate (ie, a fixed decrease in concentration per unit time independent of blood

Figure 7-8. Predicted time course of blood methanol concentration following a 120-minute exposure to 1200 and 4800 ppm of methanol vapor in the female monkey based on the toxicokinetic model reported by Burbacher *et al.* (2004) that features a saturable (Michaelis–Menten type) metabolic clearance. The left panel is a rectilinear plot of the simulated blood methanol concentration–time curves at the 2 exposure levels. The right panel shows the same simulations in a semilogarithmic plot. The washout of blood methanol following the 120-minute inhalation exposure at 1200 ppm follows a typical concave or exponential pattern in the rectilinear plot (left panel) and is linear in a semilogarithmic plot (right panel). The postexposure profile at 4800 ppm shows a linear segment during the first 120 minutes of washout and becomes exponential thereafter in the rectilinear plot (left panel). The linear segment reflects saturation of alcohol dehydrogenase, which is the principal enzyme responsible for the metabolism of methanol. The *in vivo* K_M for this simulation was set at 32.7 µg/mL. At concentrations well above K_M , the kinetics approach zero-order kinetics. At concentrations below K_M , washout kinetics become first-order with a half-life of about 60 minutes. The right panel shows a characteristic convex semilogarithmic plot for the initial phase of zero-order kinetics and becomes linear as expected for first-order kinetics when the concentration falls below K_M . It should also be noted that the maximum blood methanol following 4800 ppm exposure is predicted to be 5.9-times higher than that following 1200 ppm. Also, the area under the blood concentration–time curve (*AUC*) from time zero to 480 minutes at 4800 ppm exposure is 8-fold higher than at 1200 ppm. Under linear kinetics, the increase in maximum blood methanol and *AUC* ought to be proportionate to the dose increase, that is, a 4-fold increment. Here, we observe a more than proportionate increase in blood methanol concentration in relation to the dose, which is another hallmark of saturation kinetics.

concentration), rather than a constant fractional rate. As a result, a rectilinear plot of blood methanol concentration versus time yields an initial linear decline, whereas a convex curve is observed in the semilogarithmic plot (compare left and right panels of Fig. 7-8). In time, methanol metabolism converts to first-order kinetics when blood methanol concentration falls below K_M (ie, the Michaelis constant for the dehydrogenase enzyme), at which time blood methanol shows an exponential decline in the rectilinear plot and a linear decline in the semilogarithmic plot. Moreover, Fig. 7-8 shows the greater than proportionate increase (ie, >4-fold) in C_{max} and AUC_0^∞ as the methanol vapor concentration is raised from 1200 to 4800 ppm. It should be noted that a constant $T_{1/2}$ or k_{el} does not exist during the saturation regimen; it varies depending upon the saturating methanol dose.

In addition to the complication of dose-dependent kinetics, there are toxicants whose clearance kinetics changes over time (ie, time-dependent kinetics). A common cause of time-dependent kinetics is autoinduction of xenobiotic metabolizing enzymes; that is, the substrate is capable of inducing its own metabolism through activation of gene transcription. The classic example of autoinduction is with the antiepileptic drug, carbamazepine. Daily administration of carbamazepine leads to a continual increase in clearance and shortening in elimination half-life over the first few weeks of therapy (Bertilsson *et al.*, 1986).

Accumulation During Continuous or Intermittent Exposure

It stands to reason that continual or chronic exposure to a chemical leads to its cumulative intake and accumulation in the body. For a chemical that follows first-order elimination kinetics, the elimination rate increases as the body burden increases. Therefore, at a fixed level of continuous exposure, accumulation of a toxicant in the body eventually reaches a point when the intake rate of the toxicant equals its elimination rate, from thereon the body burden stays constant. This is referred to as the steady state. Fig. 7-9 illustrates the rise of toxicant concentration in plasma over time during continuous exposure and the eventual attainment of a plateau or the steady state. Steady-state concentration of a toxicant in plasma (C_{ss}) is related to the intake rate (R_{in}) and clearance of the toxicant.

$$C_{ss} = \frac{R_{in}}{Cl} \quad (7-16)$$

For a one-compartment model, an exponential rise in plasma concentration is expected during continuous exposure and the time it takes for a toxicant to reach steady state is governed by its elimination half-life. It takes 1 half-life to reach 50%, 4 half-lives to reach 93.8%, and 7 half-lives to reach 99.2% of steady state. Time to attainment of steady state is not dependent on the intake rate of the toxicant. The left panel of Fig. 7-9 shows the same time to 50% steady state at 3 different rates of intake; on the contrary, the steady-state concentration is strictly proportional to the intake rate. The change in clearance of a toxicant often leads to a corresponding

Figure 7-9. Accumulation of plasma toxicant concentration over time during constant, continuous exposure as a function of exposure level (left panel) and elimination half-life (right panel). These simulations are based on a 1-compartment model at a constant apparent volume of distribution. Case 1 serves as the reference with an elimination half-life set equal to 1 arbitrary time unit. In the left panel, which illustrates accumulation of toxicant as a function of exposure level, exposure level is raised by 2-fold in case 2 and lowered by 50% in case 3. The changes in eventual steady state concentration are proportional to the changes in exposure level, that is, increased by 2-fold in case 2 and decreased by 50% in case 3. During continuous exposure, 50% of steady state is achieved in 1 half-life. Near plateau or steady state (>90%) is reached after 4 half-lives. Since the elimination half-life is constant across cases 1–3 in the left panel, the time it takes to attain 50% of steady state concentration (see arrows) is the same, that is, 1 time unit. Right panel illustrates the influence of elimination half-life and clearance on accumulation at a fixed constant rate of exposure. Case 4 represents a 50% decrease in clearance and a corresponding 2-fold increase in elimination half-life compared to case 1. Case 5 represents a 2-fold increase in clearance and a corresponding 50% decrease in elimination half-life. Changes in both the time to attain steady state and the steady state concentration are evident. In case 4, the steady state concentration increased by 2-fold as a result of a 50% reduction in clearance, and the time to achieved 50% of steady state increased by 2-fold as a result of the prolonged elimination half-life. In case 5, the steady state concentration is reduced by 50%, while the time to reach 50% steady state is shortened by 50%.

Figure 7-10. Simulated accumulation of plasma concentration from occupational exposure over the cycle of a work week for 2 industrial chemicals with short and long elimination half-lives. Shading represents the exposure period during the 8-hour workday, Monday through Friday. Intake of the chemical into the systemic circulation is assumed to occur at a constant rate during exposure. Exposure is negligible over the weekend. For the chemical with the short elimination half-life of 8 hours, minimal accumulation occurs from day to day over the workdays. Near-complete washout of the chemical is observed when work resumes on Monday (see arrow). For the chemical with the long elimination half-life of 24 hours, progressive accumulation is observed over the 5 workdays. Washout of the longer half-life chemical over the weekend is incomplete; a significant residual is carried into the next work week. Because of its lower clearance, the overall *AUC* of the long half-life chemical over the cycle of a week is higher by 3-fold.

change in elimination half-life (see right panel of Fig. 7-9), in which case both the time to reach and magnitude of steady state concentration are altered. The same steady state principle applies to toxicants that exhibit multicompartmental kinetics; except that, accumulation occurs in a multiphasic fashion reflective of the multiple exponential half-lives for intercompartmental distribution and elimination. Typically, the rise in plasma concentration is relatively rapid at the beginning, being governed by the early (distribution) half-life, and becomes slower at later times when the terminal (elimination) half-life takes hold.

The concept of accumulation applies to intermittent exposure as well. Fig. 7-10 shows a typical occupational exposure scenario to volatile chemicals at the workplace over the course of a week. Whether accumulation occurs from day to day and further from week to week depends on the intervals between exposure and the elimination half-life of the chemicals involved. For a chemical with relatively short half-life compared to the interval between work shifts and the “exposure holiday” over the weekend, little accumulation is expected. In contrast, for a chemical with elimination half-life approaching or exceeding the between-shift intervals (>12–24 hours), progressive accumulation is expected over the successive workdays. Washout of the chemical may not be complete over the weekend and result in a significant carry forward of body burden into the next week. It should also be noted that the overall internal exposure as measured by the *AUC* over the cycle of a week is dependent on the toxicant clearance.

Conclusion

For many chemicals, blood or plasma chemical concentration versus time data can be adequately described by a one- or two-compartment, classic pharmacokinetic model when basic assumptions are made (eg, instantaneous mixing within compartments and first-order kinetics). In some instances, more sophisticated models with increased numbers of compartments will

be needed to describe blood or plasma toxicokinetic data; for example, if the chemical is preferentially sequestered and turns over slowly in select tissues. The parameters of the classic compartmental models are usually estimated by statistical fitting of data to the model equations using nonlinear regression methods. A number of software packages are available for both data fitting and simulations with classic compartmental models; examples include WinNonlin (Pharsight Corp, Palo Alto, CA), SAAM II (The Epsilon Group, Charlottesville, VA), ADAPT II (University of Southern California, Los Angeles, CA), and PK Solutions (Summit Research Services, Montrose, CO).

Knowledge of toxicokinetic data and compartmental modeling are useful in deciding what dose or dosing regimen of chemical to use in the planning of toxicology studies (eg, targeting a toxic level of exposure), in choosing appropriate sampling times for biological monitoring, and in seeking an understanding of the dynamics of a toxic event (eg, what blood or plasma concentrations are achieved to produce a specific response, how accumulation of a chemical controls the onset and degree of toxicity, and the persistence of toxic effects following termination of exposure).

PHYSIOLOGICAL TOXICOKINETICS

The primary difference between physiological compartmental models and classic compartmental models lies in the basis for assigning the rate constants that describe the toxicant’s movement into and out of the body compartments and its elimination (Andersen, 1991). In classic kinetics, the rate constants are defined by the data; thus, these models are often referred to as data-based models. In physiological models, the rate constants represent known or hypothesized biological processes, and these models are commonly referred to as physiologically based models. The concept of incorporating biological realism into the analysis of drug or xenobiotic distribution and elimination is not new. For example, one of the first physiological models was proposed by Teorell (1937). This model contained all the important determinants in xenobiotic disposition that are considered valid today. Unfortunately, the computational tools required to solve the underlying equations were not available at that time. With advances in computer technology, the software and hardware needed to implement physiological models are now well within the reach of toxicologists.

The advantages of physiologically based models compared with classic models are that (1) these models can describe the time course of distribution of toxicants to any organ or tissue, (2) they allow estimation of the effects of changing physiological parameters on tissue concentrations, (3) the same model can predict the toxicokinetics of toxicants across species by allometric scaling, and (4) complex dosing regimens and saturable processes such as metabolism and binding are easily accommodated (Gargas and Andersen, 1988). The disadvantages are that (1) much more information is needed to implement these models compared with classic models, (2) the mathematics can be difficult for many toxicologists to handle, and (3) values for parameters are often poorly defined in various species and pathophysiological states. Nevertheless, physiologically based toxicokinetic models are conceptually sound and are potentially useful tools for gaining rich insight into the kinetics of toxicants beyond what classic toxicokinetic models can provide.

Basic Model Structure

Physiological models are fundamentally complex compartmental models; it generally consists of a system of tissue or organ

Figure 7-11. Physiological model for a hypothetical toxicant that is soluble in water, has a low vapor pressure (not volatile), and has a relatively large molecular weight ($MW > 100$). This hypothetical toxicant is injected into the blood stream and eliminated through metabolism in the liver (K_m), biliary excretion (K_b), renal excretion (K_r) into the urine, and fecal excretion (K_i). The toxicant can also undergo enterohepatic circulation (K_{ec}). Perfusion-limited compartments are noted in red and diffusion-limited compartments are noted in blue.

compartments that are interconnected by the circulatory network. If necessary, each tissue or organ compartments can further be divided into extracellular and intracellular compartments to describe movement of toxicant at the cellular level. The exact model structure, or how the compartments are organized and linked together, depends on both the toxicant and the organism being studied. For example, a physiological model describing the disposition of a toxicant in fish would require a description of the gills (Nichols *et al.*, 1994), whereas a model for the same toxicant in mammals would require a lung compartment (Ramsey and Andersen, 1984). Model structures can also vary with the toxicants being studied. For example, a model for a nonvolatile, water-soluble chemical, which might be administered by iv injection (Fig. 7-11), has a structure different from that of a model for a volatile organic chemical for which inhalation is the likely route of exposure (Fig. 7-12). The route of administration is not the only difference between these 2 models. For example, the first model has a compartment for the intestines, because biliary excretion, fecal elimination, and enterohepatic circulation are presumed important in the disposition of this chemical. The second model has a compartment for fat because fat is an important storage organ for organics. However, the models are not completely different. Both contain a liver compartment because hepatic metabolism of each chemical is an important element of its disposition. It is important to realize that there is no generic physiological model. Models are simplifications of reality and should contain elements considered to represent the essential disposition features of a toxicant.

In view of the fact that physiological modeling requires more effort than does classic compartmental modeling, what then accounts for the popularity of this approach among toxicologists?

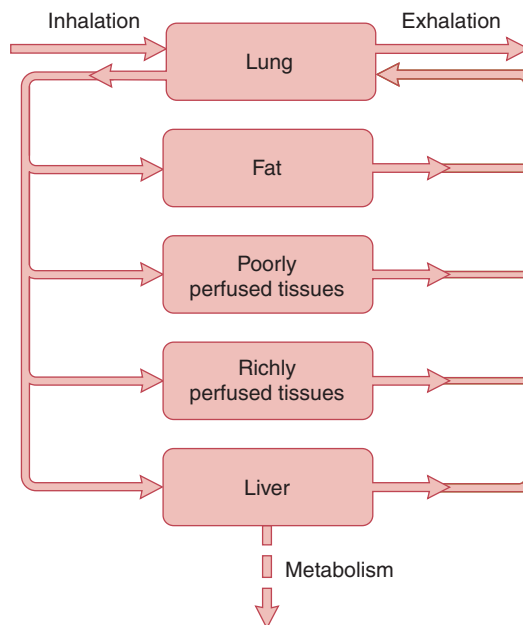

Figure 7-12. Physiological model for a typical volatile organic chemical. Chemicals for which this model would be appropriate have low molecular weights ($MW < 100$), are soluble in organic solvents, and have significant vapor pressures (volatile). The main route of its intake is via inhalation and absorption by the lungs. Transport of chemical throughout the body by blood is depicted by the arrows. Elimination of chemical as depicted by the model includes metabolism (dashed arrow) and exhalation (arrows indicate ventilation of the lung). All compartments are perfusion-limited.

The answer lies in the potential predictive power of physiological models. Toxicologists are constantly faced with the issue of extrapolation in risk assessments—from laboratory animals to humans, from high to low doses, from acute to chronic exposure, and from single chemicals to mixtures. Because the kinetic constants in physiological models represent measurable biological or chemical processes, the resultant physiological models have the potential for extrapolation from observed data to predicted scenarios.

One of the best illustrations of the predictive power of physiological models is their ability to extrapolate kinetic behavior from laboratory animals to humans. For example, physiological models developed for styrene and benzene correctly simulate the concentration of each chemical in the blood of both rodents and humans (Ramsey and Andersen, 1984; Travis *et al.*, 1990). Simulations are the outcomes or results (such as a chemical's concentration in blood or tissue) of numerically solving the model equations over a time period of concern, using a set of initial (such as level of exposure) or input conditions (such as route of exposure) and parameter values appropriate for the species (such as organ weights and blood flow). Both styrene and benzene are volatile organic chemicals; thus, the model structures for the kinetics of both chemicals in rodents and humans are identical to that shown in Fig. 7-12. However, the parameter values for rodents and humans are different. Humans have larger body weights than rodents, and thus weights of organs such as the liver are larger. Because humans are larger, they also breathe more air per unit of time than do rodents, and a human heart pumps a larger volume of blood per unit of time than does that of a rodent, although the rodent's heart beats more times in the same period. The parameters that describe the chemical behavior of styrene and benzene, such as solubility in tissues, are similar in the rodents and human

models. This is often the case because the composition of tissues in different species is similar.

For both styrene and benzene, there are experimental data for humans and rodents and the model simulations can be compared with the actual data to see how well the model has performed (Ramsey and Andersen, 1984; Andersen *et al.*, 1984; Travis *et al.*, 1990). The conclusion is that the same model structure is capable of describing the chemicals' kinetics in two different species. Because the parameters underlying the model structure represent measurable biological and chemical determinants, the appropriate values for those parameters can be chosen for each species, forming the basis for successful interspecies extrapolation. Even though the same model structure is used for both rodents and humans, the simulated and the observed kinetics of both chemicals differ between rats and humans. The terminal half-life of both organics is longer in humans compared with rats. This longer half-life for humans is due to the fact that clearance rates for smaller species are faster than those for larger ones. Even though the larger species breathes more air or pumps more blood per unit of time than does the smaller species, blood flows and ventilation rates per unit of body mass are greater for the smaller species. The smaller species has more breaths per minute or heartbeats per minute than does the larger species, even though each breath or stroke volume is smaller. The faster flows per unit mass result in a more efficient delivery of a chemical to organs responsible for elimination. Thus, a smaller species can eliminate the chemical faster than a larger one can. Because the parameters in physiological models represent real, measurable values, such as blood flows and ventilation rates; the same model structure can resolve such disparate kinetic behaviors among species.

Compartments

The basic unit of the physiological model is the lumped compartment, which is often depicted as a box in a graphical scheme (Fig. 7-13). A compartment represents a definable anatomical site or tissue type in the body that acts as a unit in effecting a measurable kinetic process (Rowland, 1984, 1985). A compartment may represent a particular structure or functional portion of an organ, a segment of blood vessel with surrounding tissue, an entire discrete organ such as the liver or kidney, or a widely distributed tissue type such as fat or skin. Compartments usually consist of three individual well-mixed regions, or subcompartments, that correspond

Figure 7-13. Schematic representation of a lumped tissue compartment in a physiological model. The blood capillary and cell barriers separating the vascular, interstitial, and intracellular subcompartments are depicted in heavy black lines. The vascular and interstitial subcompartments are often combined into a single extracellular subcompartment. Q_t is the blood perfusion flow, C_{in} is the toxicant's concentration in the blood entering the compartment, and C_{out} is the toxicant's concentration in the blood leaving the compartment.

to specific physiological spaces or regions of the organ or tissue. These subcompartments are (1) the vascular space through which the compartment is perfused with blood, (2) the interstitial space that surrounds the cells, and (3) the intracellular space representing the cells in the tissue (Gerlowski and Jain, 1983).

As shown in Fig. 7-13, the toxicant enters the vascular subcompartment at a certain rate in mass per unit of time (eg, mg/h). The rate of entry is a product of the blood flow rate to the tissue (Q_t in L/h) and the concentration of the toxicant in the blood entering the tissue (C_{in} in mg/L). Within the compartment, the toxicant moves from the vascular space to the interstitial space at a certain net rate ($Flux_1$) and moves from the interstitial space to the intracellular space at a different net rate ($Flux_2$). Some toxicants can bind to protein components; thus, within a compartment there may be both free and bound toxicants. The toxicant leaves the vascular space at a certain venous concentration (C_{out}). C_{out} is equal to the concentration of the toxicant in the vascular space assuming a well-mixed compartment.

Parameters

The most common types of parameters, or information required, in physiological models are anatomic, physiological, thermodynamic, and transport.

Anatomic Anatomic parameters are used to describe the physical size of various compartments. The size is generally specified as a volume (milliliters or liters) because a unit density is assumed even though weights of organs and tissues are most frequently obtained experimentally. If a compartment contains subcompartments such as those in Fig. 7-13, those volumes also must be known. Volumes of compartments often can be obtained from the literature or from specific toxicokinetic experiments. For example, kidneys, liver, brain, and lungs can be weighed. Obtaining precise data for volumes of compartments representing widely distributed tissues such as fat or muscle is more difficult. If necessary, these tissues can be removed by dissection and weighed. Among the numerous sources of general information on organ and tissue volumes across species, Brown *et al.* (1997) is a good starting point.

Physiological Physiological parameters encompass a wide variety of processes in biological systems. The most commonly used physiological parameters are blood flows and lung ventilation. The blood flow rate (Q_t in volume per unit time, such as mL/min or L/h) to individual compartments must be known. Additionally, information on the total blood flow rate or *cardiac output* (Q_c) is necessary. If inhalation is the route for exposure to the chemical or is a route of elimination, the alveolar ventilation rate (Q_p) also must be known. Blood flow rates and ventilation rates can be taken from the literature or can be obtained experimentally.

Parameters for renal excretion and hepatic metabolism are another subset of physiological parameters, and are required, if these processes are important in describing the elimination of a chemical. For example, glomerular filtration rate and renal tubular transport parameters are required to describe renal clearance. If a chemical is known to be metabolized via a saturable process, both V_{max} (the maximum rate of metabolism) and K_M (the concentration of chemical at one-half V_{max}) for each of the enzymes involved must be obtained so that elimination of the chemical by metabolism can be described in the model. In principle, these parameters can be determined from *in vitro* metabolism or transport studies with freshly isolated cells, cultured cells, or recombinant DNA expression systems; metabolic studies are also feasible with tissue homogenates or cellular fractions containing the metabolic enzymes (eg, microsomes for cytochrome P450 enzymes and uridine diphosphate

glucuronosyltransferases). Appropriate *in vitro*–*in vivo* scaling is required (Iwatsubo *et al.*, 1997; MacGregor *et al.*, 2001; Miners *et al.*, 2006). Although there have been examples of remarkable success with quantitative prediction of *in vivo* hepatic clearance based on *in vitro* metabolic data, there are also notable failures. There is still very limited experience with *in vitro*–*in vivo* scaling of renal or hepatic transporter function. Unfortunately, estimation of metabolic or transport parameters from *in vivo* studies is also fraught with difficulties, especially when multiple metabolic pathways and enzymes are involved in the metabolic clearance of a substrate, or when parallel and/or sequential transport processes mediate the passage of a solute across a cellular barrier. Estimation of metabolic and excretory parameters remains a challenging aspect of physiologically based toxicokinetic modeling.

Thermodynamic Thermodynamic parameters relate the *total* concentration of a toxicant in a tissue (C_t) to the concentration of *free* toxicant in that tissue (C_f). Two important assumptions are that (1) total and free concentrations are in equilibrium with each other, and (2) only free toxicant can be exchanged between the tissue sub-compartments (Lutz *et al.*, 1980). Most often, total concentration is measured experimentally; however, it is the free concentration that is available for diffusion across membrane barriers, binding to proteins, metabolism, or carrier-mediated transport. Various mathematical expressions describe the relationship between these two entities. In the simplest situation, the toxicant is a freely diffusible water-soluble chemical that does not bind to any molecules. In this case, free concentration of the chemical is equal to the total concentration of the chemical in the tissue: $C_t = C_f$. The affinity of toxicants for tissues of different composition varies. The extent to which a toxicant partitions into a tissue is directly dependent on the composition of the tissue and usually independent of the concentration of the toxicant. Thus, the relationship between free and total concentration becomes one of proportionality: $C_t = C_f \cdot P_t$; P_t is in effect the partition coefficient between total concentration in the tissue and freely diffusible concentration in the interstitial fluid or plasma water. Knowledge of the value of P_t permits an indirect calculation of the free concentration of toxicant in the tissue or $C_f = C_t/P_t$, assuming intracellular, interstitial and plasma concentrations of free drug are equal (ie, no concentrative transport across barriers in either direction). P_t is most often determined from tissue distribution studies in animals, preferably at steady state during continuous *iv* infusion of the toxicant. In some cases, it has been successfully estimated from *in vitro* binding studies with human or animal tissues or tissue fractions (Lin *et al.*, 1982; MacGregor *et al.*, 2001).

Table 7-4 compares the partition coefficients for a number of toxic volatile organic chemicals. The larger values for the fat-to-blood partition coefficients compared with those for other tissues suggest that these chemicals distribute into fat to a greater extent than they distribute into other tissues. This has been observed

Table 7-4

Partition Coefficients for Four Volatile Organic Chemicals in Several Tissues

CHEMICAL	BLOOD/AIR	MUSCLE/BLOOD	FAT/BLOOD
Isoprene	3	0.67	24
Benzene	18	0.61	28
Styrene	40	1	50
Methanol	1350	3	11

experimentally. Fat and fatty tissues, such as bone marrow, contain higher concentrations of benzene than do tissues such as liver and blood. Similarly, styrene concentrations in fatty tissue are higher than styrene concentrations in other tissues. It should be noted that lipophilic organic compounds often can bind to plasma proteins and/or blood cell constituents, in which case the observed tissue/blood partition coefficients will be a function of both the tissue and blood partition coefficient (ie, P_t/P_b). Hence, partitioning or binding to blood constituents (P_b) must be known in order to estimate the true thermodynamic partitioning coefficient for a tissue or the free toxicant concentration at equilibrium. P_b can be determined from *in vitro* studies of blood cells to plasma distribution and plasma protein binding of the toxicant.

A more complex relationship between the free concentration and the total concentration of a chemical in tissues is also possible. For example, the chemical may bind to saturable binding sites on tissue components. In these cases, nonlinear functions relating the free concentration in the tissue to the total concentration are necessary. Examples in which more complex binding has been used are physiological models for dioxin and *tertiary*-amyl methyl ether (Andersen *et al.*, 1993; Collins *et al.*, 1999).

Transport Passage of a toxicant across a biological membrane may occur by passive diffusion, carrier-mediated transport involving either facilitated or active transporters, or a combination thereof (Himmelstein and Lutz, 1979). The simplest of these processes—passive diffusion is a first-order process described by Fick's law of diffusion. Diffusion of a toxicant occurs during its passage across the blood capillary endothelium (Flux₁ in Fig. 7-13) and across cell barriers (Flux₂ in Fig. 7-13). Flux refers to the rate of transfer of a chemical across a boundary. For simple diffusion, the net flux (mg/h) from one side of a membrane to the other is governed by the barrier permeability and the toxicant concentration gradient.

$$\text{Flux} = PA \cdot (C_1 - C_2) = PA \cdot C_1 - PA \cdot C_2 \quad (7-17)$$

The term PA is often called the *permeability*–*area product* for the membrane or cellular barrier in flow units (eg, L/h), and is a product of the barrier permeability coefficient (P in velocity units, eg, $\mu\text{m}/\text{h}$) for the toxicant and the total barrier surface area (A , in μm^2). The permeability coefficient takes into account the diffusivity of the specific toxicant and the thickness of the cell membrane. C_1 and C_2 are the respective *free* concentrations of the toxicant in the originating and receiving compartments. Diffusional flux is enhanced when the barrier thickness is small, the barrier surface area is large, and a large concentration gradient exists. Membrane transporters offer an additional route of entry into cells, and allow more effective tissue penetration for toxicants that have limited passive permeability. Alternately, the presence of efflux transporters at epithelial or endothelial barriers can limit toxicant penetration into critical organs, even for highly permeable toxicant (eg, P-glycoprotein-mediated efflux functions as part of the blood–brain barrier). For both transporter-mediated influx and efflux processes, the kinetics is saturable and can be characterized by T_{max} (the maximum transport rate) and K_T (the concentration of toxicant at one-half T_{max}) for each of the transporters involved. In principle, kinetic parameters for passive permeability or carrier-mediated transport can be estimated from *in vitro* studies with tissue slices (eg, with tetraethylammonium ion; Mintun *et al.*, 1980) or cultured cell monolayer systems. However, the predictability and applicability of such *in vitro* approaches for physiological modeling has not been systematically evaluated (MacGregor *et al.*, 2001). At this time, the transport parameters have to be estimated from *in vivo* data, which are at times difficult and carry a significant degree of uncertainty.

There are two limiting conditions for the uptake of a toxicant into tissues: perfusion-limited and diffusion-limited. An understanding of the assumptions underlying the limiting conditions is critical because the assumptions change the way in which the model equations are written to describe the movement of a toxicant into and out of the compartment.

Perfusion-Limited Compartments

A perfusion-limited compartment, alternately referred to as blood flow-limited or simply flow-limited compartment, describes the situation when permeability across the cellular or membrane barriers (PA) for a particular toxicant is much greater than the blood flow rate to the tissue (Q_t), that is, $PA_1 \gg Q_t$. In this case, uptake of toxicant by tissue subcompartments is limited by the rate at which the toxicant is presented to the tissue via the arterial inflow, and not by the rate at which the toxicant penetrates through the vascular endothelium, which is fairly porous in most tissues, or gains passage across the cell membranes. As a result, equilibration of a toxicant between the blood in the tissue vasculature and the interstitial subcompartment is maintained at all times, and the two subcompartments are usually lumped together as a single extracellular compartment. An important exception to this vascular-interstitial equilibrium relationship is in the brain, where the capillary endothelium with its tight junctions poses a diffusional barrier between the vascular space and the brain interstitium. Furthermore, as indicated in Fig. 7-13, the cell membrane separates the extracellular compartment from the intracellular compartment. The cell membrane is the most crucial diffusional barrier in a tissue. Nonetheless, for molecules that are very small (molecular weight < 100) or lipophilic ($\log P > 2$), cellular permeability generally does not limit the rate at which a molecule moves across cell membranes. For these molecules, flux across the cell membrane is fast compared with the tissue perfusion rate ($PA_2 \gg Q_t$), and the molecules rapidly distribute throughout the subcompartments. In this case, free toxicant in the intracellular compartment is always in equilibrium with the extracellular compartment, and these tissue subcompartments can be lumped as a single compartment. Such a flow-limited tissue compartment is shown in Fig. 7-14. Movement into and out of the entire tissue compartment can be described by a single equation.

$$V_t \cdot \frac{dC_t}{dt} = Q_t \cdot (C_{in} - C_{out}) \quad (7-18)$$

where V_t is the volume of the tissue compartment, C_t is the toxicant concentration in the compartment ($V_t \cdot C$ equals the amount of toxicant in the compartment), $V_t \cdot dC_t/dt$ is the change in the amount of toxicant in the compartment with time, expressed as mass per unit of time, Q_t is blood flow to the tissue, C_{in} is the toxicant

Figure 7-14. Schematic representation of a tissue compartment that features blood flow-limited uptake kinetics. Rapid exchange of toxicant between the extracellular space (blue) and intracellular space (light blue), unhindered by a significant diffusional barrier as symbolized by the dashed line, allows equilibrium to be maintained between the two subcompartments at all times. In effect, a single compartment represents the tissue distribution of the toxicant. Q_t is blood flow, C_{in} is the toxicant concentration entering the compartment via the arterial inflow, and C_{out} is the toxicant concentration leaving the compartment in the venous outflow.

concentration entering the compartment, and C_{out} is the toxicant concentration leaving the compartment. Equations of this type are called mass-balance differential equations. Differential refers to the term dC_t/dt . Mass balance refers to the requirement that the rate of change in the amount of toxicant in a compartment (left-hand side of Equation (7-18)) equals the difference in the rate of entry via arterial inflow and the rate of departure via venous outflow (right-hand side of Equation (7-18)).

In the perfusion-limited case, the concentration of toxicant in the venous drainage from the tissue is equal to the concentration of toxicant in the tissue when the toxicant is not bound to blood constituents (ie, $C_{out} = C_t = C_p$). As was noted previously, when there is binding of toxicant to tissue constituents, C_f (or C_{out}) can be related to the total concentration of toxicant in the tissue through a simple linear partition coefficient, $C_{out} = C_t = C_t/P_t$. In this case, the differential equation describing the rate of change in the amount of a toxicant in a tissue becomes

$$V_t \cdot \frac{dC_t}{dt} = Q_t \cdot \left[C_{in} - \frac{C_t}{P_t} \right] \quad (7-19)$$

In the event the toxicant does bind to blood constituents, blood partitioning coefficient needs to be recognized in the mass-balance equation.

$$V_t \cdot \frac{dC_t}{dt} = Q_t \cdot \left[C_{in} - \frac{C_t}{P_t/P_b} \right] \quad (7-20)$$

The physiological model shown in Fig. 7-12, which was developed for volatile organic chemicals such as styrene and benzene, is a good example of a model in which all the compartments are described as flow-limited. Distribution of a toxicant in all the compartments is described by using equations of the type noted above. In a flow-limited compartment, the assumption is that the concentrations of a toxicant in all parts of the tissue are in equilibrium. For this reason, the compartments are generally drawn as simple boxes (Fig. 7-12) or boxes with dashed partitioning lines that symbolize the equilibrium between the intracellular and extracellular subcompartments (Fig. 7-14). Additionally, with a flow-limited model, estimates of fluxes between subcompartments are not required to develop the mass-balance differential equation for the compartment. Given the challenges in measuring flux across the vascular endothelium and cell membrane, this is a simplifying assumption that significantly reduces the number of parameters required in the physiological model.

Diffusion-Limited Compartments

When uptake of a toxicant into a compartment is governed by its diffusion or transport across cell membrane barriers, the model is said to be diffusion-limited or barrier-limited. Diffusion-limited uptake or release occurs when the flux, or the transport of a toxicant across cell barriers, is slow compared with blood flow to the tissue. In this case, the permeability–area product is small compared with blood flow, that is, $PA \ll Q_t$. The distribution of large and/or polar molecules into tissue cells is likely to be limited by the rate at which the molecules pass through cell membranes. In contrast, entry into the interstitial space of the tissue through the leaky capillaries of the vascular space is usually rapid even for large molecules. Fig. 7-15 shows the structure of such a compartment. The toxicant concentrations in the vascular and interstitial spaces are in equilibrium and make up the extracellular subcompartment, where uptake from the incoming blood is flow-limited. The rate of toxicant uptake across the cell membrane from the extracellular space

Figure 7-15. Schematic representation of a tissue compartment that features membrane-limited uptake kinetics. Perfusion of blood into and out of the extracellular compartment is depicted by thick arrows. Transmembrane transport (flux) from the extracellular to the intracellular subcompartment is depicted by thin arrows. Q_t is blood flow, C_{in} is toxicant concentration entering the compartment, and C_{out} is toxicant concentration leaving the compartment.

into the intracellular space is limited by membrane permeability. Two mass-balance differential equations are necessary to describe the events in these 2 subcompartments:

$$\begin{aligned} \text{Extracellular: } V_{t1} \cdot \frac{dC_{t1}}{dt} &= Q_t \cdot (C_{in} - C_{out}) \\ &- PA_t \cdot \left(\frac{C_{t1}}{P_{t1}} \right) + PA_t \cdot \left(\frac{C_{t2}}{P_{t2}} \right) \end{aligned} \quad (7-21)$$

$$\begin{aligned} \text{Intracellular: } V_{t2} \cdot \frac{dC_{t2}}{dt} &= PA_t \cdot \left(\frac{C_{t1}}{P_{t1}} \right) \\ &- PA_t \cdot \left(\frac{C_{t2}}{P_{t2}} \right) \end{aligned} \quad (7-22)$$

Q_t is blood flow, and C is the toxicant concentration in the entering blood (in), exiting blood (out), tissue extracellular space (t1), or tissue intracellular space (t2). The subscript (ti) for the PA term acknowledges the fact that PA , reflecting either passive diffusion and/or carrier-mediated processes, can differ between tissues. Both equations feature fluxes or transfers across the cell membrane that are driven by free concentration. Hence, partition coefficients are needed to convert extracellular and intracellular tissue concentration to their corresponding free concentration. C_{out} in Equation (7-21) is related to $C_{t1}/(P_{t1}/P_b)$; the blood partitioning coefficient P_b is required if the toxicant binds to plasma proteins and blood cells. The physiological model in Fig. 7-11 is composed of two diffusion-limited compartments each of which contain two subcompartments—extracellular and intracellular space, and several perfusion-limited compartments.

Specialized Compartments

Lung The inclusion of a lung compartment in a physiological model is an important consideration because inhalation is a common route of exposure to many volatile toxic chemicals. Additionally, the lung compartment serves as an instructive example of the assumptions and simplifications that can be incorporated into physiological models while maintaining the overall objective of describing processes and compartments in biologically relevant terms. For example, although lung physiology and anatomy are complex, Haggard (1924) developed a simple approximation that sufficiently describes the uptake of many volatile chemicals by the lungs. A diagram of this simplified lung compartment is shown in Fig. 7-16. The assumptions inherent in this compartment description are as follows: (1) ventilation is continuous, not cyclic; (2) conducting airways (nasal passages, larynx, trachea, bronchi, and bronchioles) function as inert tubes, carrying the vapor to the alveoli where gas exchange occurs; (3) diffusion of vapor across the alveolar epithelium and capillary walls is rapid compared with

Figure 7-16. Simple model for exchange of volatile chemicals in the alveolar region of the respiratory tract. Rapid exchange of toxicant in the simplified lung compartment between the alveolar gas (blue) and the pulmonary blood (light blue) maintains an equilibrium between them as symbolized by the dashed line. Q_p is alveolar ventilation (L/h); Q_c is cardiac output (L/h); C_{inh} is inhaled vapor concentration (mg/L); C_{art} is concentration of chemical in the arterial blood; C_{ven} is concentration of chemical in the mixed venous blood. The equilibrium relationship between the chemical in the alveolar air (C_{alv}) and the chemical in the arterial blood (C_{art}) is determined by the blood/air partition coefficient $P_{b/a}$, that is, $C_{alv} = C_{art}/P_{b/a}$.

blood flow through the alveolar region; (4) all chemicals disappearing from the inspired air appears in the arterial blood (ie, there is no hold-up of chemical in the lung tissue and insignificant lung mass); and (5) vapor in the alveolar air and arterial blood within the lung compartment are in rapid equilibrium and are related by $P_{b/a}$, the blood/air partition coefficient (eg, $C_{alv} = C_{art}/P_{b/a}$). $P_{b/a}$ is a thermodynamic parameter that quantifies the equilibrium partitioning of a volatile chemical between blood and air.

In the lung compartment depicted in Fig. 7-16, the rate of inhalation of a volatile chemical is controlled by the ventilation rate (Q_p) and the inhaled concentration (C_{inh}). The rate of exhalation of the chemical is a product of the ventilation rate and the chemical's concentration in the alveoli (C_{alv}). Chemical also can enter the lung compartment via mixed venous blood returning from the heart, at a rate represented by the product of cardiac output (Q_c) and the concentration of chemical in venous blood (C_{ven}). Chemical leaves the lungs via the blood at a rate determined by both cardiac output and the concentration of chemical in arterial blood (C_{art}). Putting these four processes together, a mass-balance differential equation can be written for the rate of change in the amount of chemical in the lung compartment (L):

$$\frac{dL}{dt} = Q_p \cdot (C_{inh} - C_{alv}) + Q_c \cdot (C_{ven} - C_{art}) \quad (7-23)$$

Because of these assumptions, during continuous exposure at steady state the rate of change in the amount of chemical in the lung compartment becomes zero ($dL/dt = 0$). C_{alv} can be replaced by $C_{art}/P_{b/a}$, and the differential equation can be solved for the arterial blood concentration:

$$C_{art} = \frac{Q_p \cdot C_{inh} + Q_c \cdot C_{ven}}{Q_c + Q_p/P_{b/a}} \quad (7-24)$$

This algebraic equation is incorporated into physiological models for many volatile organics. In this case, the lung is viewed as a portal of entry and not as a target organ; the concentration of a chemical delivered to other organs by the arterial blood is of primary interest. The assumptions of continuous ventilation, rapid equilibration with arterial blood, and no hold-up in the lung tissues have worked extremely well with many volatile organics, especially relatively lipophilic volatile solvents. Indeed, the use of these assumptions simplifies and speeds model calculations and may be entirely adequate for describing the toxicokinetic behavior of relatively inert vapors with low water solubility.

Inspection of the equation for calculating the arterial concentration of the inhaled organic vapor indicates that $P_{b/a}$, the blood/air

partition coefficient of the chemical, becomes an important term for simulating the uptake of various volatile organics. As the value for $P_{b/a}$ increases, the maximum concentration of the chemical in the blood increases. Additionally, the time to reach the steady state concentration and the time to clear the chemical also increase with increasing $P_{b/a}$. Fortunately, $P_{b/a}$ is readily measured by using in vitro techniques in which a volatile chemical in air is equilibrated with blood in a closed system, such as a sealed vial (Gargas and Andersen, 1988).

Liver The liver is almost always featured as a distinct compartment in physiological models because biotransformation is an important route of elimination for many toxicants and the liver is considered the major organ for biotransformation of xenobiotics. A simple compartmental structure for the liver is depicted in Fig. 7-17, where uptake into the liver compartment is assumed to be flow-limited. This liver compartment is similar to the general tissue compartment in Fig. 7-14, except that the liver compartment contains an additional process for metabolic elimination. Under first-order elimination, the rate of hepatic metabolism (R) by the liver can be presented as

$$R = Cl_1 \cdot C_f \quad (7-25)$$

where C_f is the free concentration of toxicant in the liver (mg/L), and Cl_1 is the clearance of free toxicant within the liver (L/h). The latter parameter is conceptually the same as the intrinsic hepatic clearance term ($Cl_{int,h}$) in Equation (7-12). In the case of a single enzyme mediating the biotransformation and Michaelis–Menten kinetics are obeyed, Cl_1 is related to the maximum rate of metabolism, V_{max} (in mg/h) and the Michaelis constant, K_M (in mg/L) (Andersen, 1981). As a result, the rate of hepatic metabolism can be expressed in terms of the Michaelis parameters.

$$R = \left[\frac{V_{max}}{K_M + C_f} \right] \cdot C_f \quad (7-26)$$

Under nonsaturating or first-order condition (ie, $C_f \ll K_M$), Cl_1 becomes equal to the ratio of V_{max}/K_M . Because many toxicants at high exposure levels display saturable metabolism, the above equation is often invoked for simulation of toxicant disposition across a wide range of doses.

Other, more complex expressions for metabolism also can be incorporated into physiological models. Bi-substrate

Figure 7-17. Schematic representation of a flow-limited liver compartment in which metabolic elimination occurs. R , in milligrams per hour, is the rate of metabolism. Q_l is hepatic blood flow, C_{in} is toxicant concentration entering the liver compartment, and C_{out} is chemical concentration out of the liver compartment. It should be noted that the liver receives blood from 2 sources, arterial inflow via hepatic artery and outflow from the upper mesentery via portal vein. This dual inflow is featured in the physiological model featuring enterohepatic circulation in Fig. 7-11. Inflow via hepatic artery is often ignored, as in this case and in the physiological model shown in Fig. 7-12, because of its relatively small flow rate compared to portal flow.

second-order reactions, reactions involving the destruction of enzymes, inhibition of enzymes, or the depletion of cofactors, have been simulated using physiological models. Metabolism can be also included in other compartments in much the same way as described for the liver.

Blood In a physiological model, the tissue compartments are linked together by the circulatory network. Figs. 7-11 and 7-12 represent different approaches toward describing the circulatory network in physiological models. In general, the arterial system delivers a chemical into various tissues. Exceptions are the liver, which receives arterial and portal blood, and the lungs, which receive mixed venous blood from the right cardiac ventricle. In the body, the venous blood supplies draining from tissue compartments eventually merge in the vena cava and heart chambers to form mixed venous blood. In Fig. 7-11, a blood compartment is created in which the input is the sum of the toxicant outflow from each compartment ($Q_i \cdot C_{vi}$). Outflow from the blood compartment is a product of the blood concentration in the compartment and the total cardiac output ($Q_c \cdot C_{bl}$). The mass-balance differential equation for the blood compartment in Fig. 7-11 is as follows:

$$V_{bl} \cdot \frac{dC_{bl}}{dt} = (Q_{br} \cdot C_{vbr} + Q_{ot} \cdot C_{vot} + Q_k \cdot C_{vk} + Q_l \cdot C_{vl}) - Q_c \cdot C_{bl} \quad (7-27)$$

where V_{bl} is the volume of the blood compartment; C is concentration; Q is blood flow; bl, br, ot, k, and l represent the blood, brain, other tissues, kidney, and liver compartments, respectively; and vbr, vot, vk, and vl represent the venous blood leaving the organs. Q_c is the total blood flow equal to the sum of the venous blood flows from each organ.

In contrast, the physiological model in Fig. 7-12 does not feature an explicit blood compartment. For simplicity, the blood volumes of the heart and the major blood vessels that are not within organs are assumed to be negligible. The venous concentration of a chemical returning to the lungs is simply the weighted average of the concentrations in the venous blood emerging from the tissues.

$$C_v = (Q_l \cdot C_{vl} + Q_{rp} \cdot C_{vrp} + Q_{pp} \cdot C_{vpp} + Q_f \cdot C_{vf}) / Q_c \quad (7-28)$$

where C is concentration; Q is blood flow; l, rp, pp, and f represent the liver, richly perfused, poorly perfused, and fat tissue compartments, respectively; and vl, vrp, vpp, and vf represent the venous blood leaving the corresponding organs. Q_c is the total blood flow equal to the sum of the blood flows exiting each organ.

In the physiological model in Fig. 7-12, the blood concentration entering each tissue compartment is the arterial concentration (C_{art}) that was calculated above for the lung compartment (Equation (7-24)). The decision to use one formulation as opposed to another to describe blood in a physiological model depends on the role the blood plays in disposition and the type of application. If the toxicokinetics after iv injection is to be simulated or if binding to or metabolism by blood components is suspected, a separate compartment for the blood that incorporates these additional processes is required. A blood compartment is obviously needed if the model were developed to explain a set of blood concentration–time data for a toxicant. However, if blood is simply a conduit to the other compartments, as in the case for inhaled volatile organics shown in Fig. 7-12, the algebraic solution is acceptable.

Fig. 7-18 shows the application of physiological modeling in elucidating the disposition fate of methylmercury and its

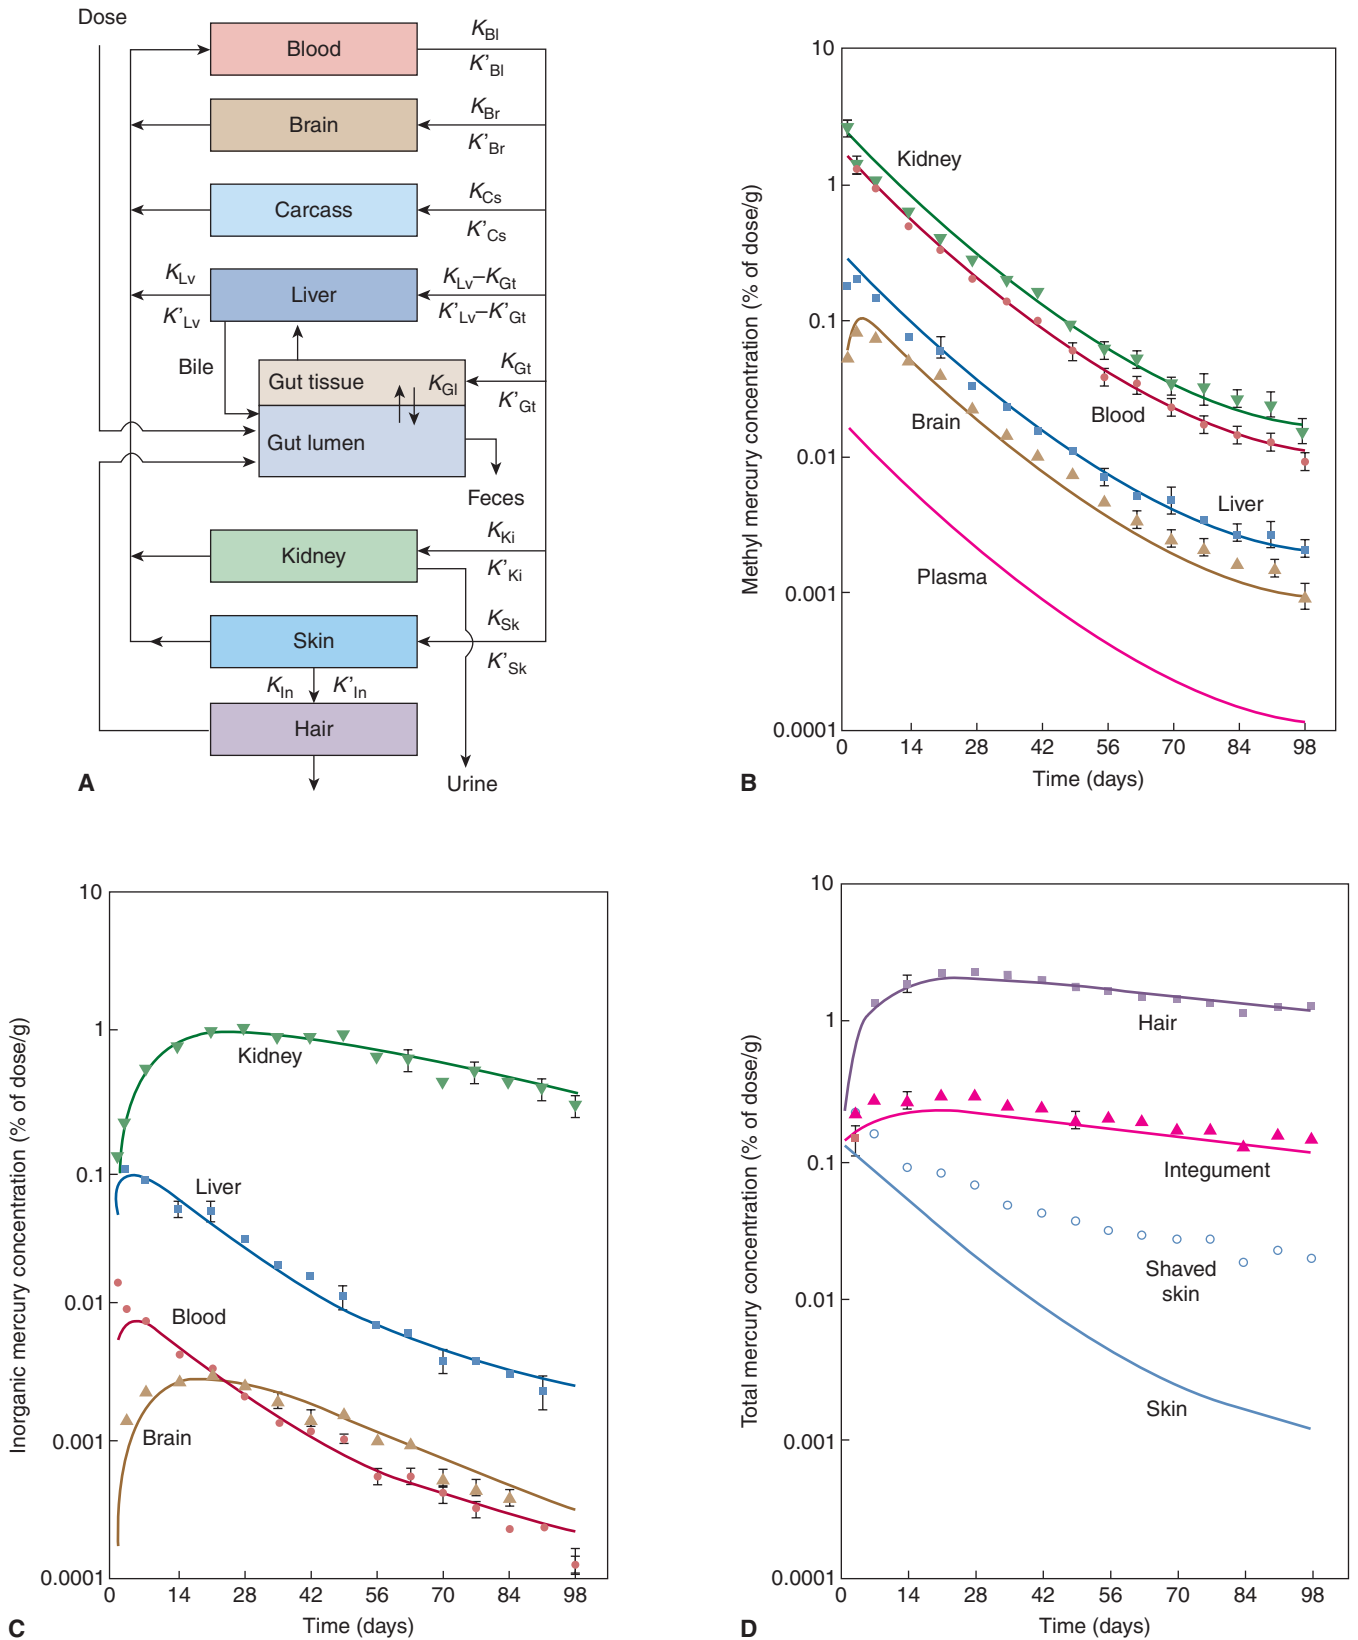

Figure 7-18. Model simulations compared with experimental data obtained in growing adult rats dosed orally with ^{203}Hg -labeled methylmercury chloride. Panel (A) shows the physiological model for methylmercury and its demethylated product, inorganic mercury. Primed symbols denote the parameters for inorganic mercury. Panels (B) and (C) show the respective time course of methylmercury and inorganic mercury concentration in blood, liver, kidneys, and the brain. Panel (D) shows the slow accumulation of total mercury in hair and skin, or the integument (skin plus hair). (Reprinted from Farris *et al.*, 1993, with permission from Elsevier.)

demethylated product, inorganic mercury following a single peroral administration in the growing adult rat (Farris *et al.*, 1993). The model scheme presented in Panel A for both the organic and inorganic forms of mercury has the following unique features: (1) increase in compartment size due to growth over the long duration of the tissue washout experiment; (2) mercury enters the gut lumen via biliary excretion and secretory transport from gut tissue to lumen, some of which is reabsorbed; (3) uptake of methylmercury from blood into tissues, except for the brain, is assumed to be rate-limited by plasma flow because of sequestration of mercury in rat erythrocytes and its slow release; (4) uptake of methylmercury across the blood–brain barrier is rate-limited by transport; (5) uptake of inorganic mercury into all tissues, except the liver, is limited by permeability/transport; (6) mercury is transferred from skin into hair, where it is irreversibly bound; and (7) mercury in hair is either shed or ingested by the animal during grooming. The model simulations displayed in Panels B, C, and D show two prominent features of methylmercury disposition: (1) methylmercury is rapidly demethylated to inorganic mercury, which is slowly eliminated from the brain and the kidneys, two major sites of methylmercury toxicities; and (2) a significant portion of mercury is sequestered in hair and the ingestion of hair by the animal contributes to the remarkable persistence of mercury in the rat. This example illustrates the capability of physiological models to deal with the varied and complex disposition kinetics of toxicants from a wide range of sources under a multitude of experimental and environmental exposure scenarios.

Conclusions

The second section provides an introduction to the simpler elements of physiological models and the important assumptions that underlie model structures. For more detailed aspects of physiological modeling, the readers can consult several in-depth and well-annotated reviews on physiologically based toxicokinetic models (Clewell and Anderson, 1994, 1996; O’Flaherty, 1998; Krishnan and Anderson, 2001; Krishnan *et al.*, 2002; Andersen, 2003). Computer softwares are available for numerically integrating the system of differential equations that form the models. Investigators have successfully used Advanced Continuous Simulation Language (Pharsight Corp, Palo Alto, CA), Simulation Control Program (Simulation Resources, Inc, Berrien Springs, MI), MATLAB (The MathWorks, Inc, Natick, MA), and SAS software applications to name a few. Choice of software depends on prior experience, familiarity with the computer language used, and cost of the software package.

The field of physiological modeling continues to evolve as toxicologists and pharmacologists develop increasingly more sophisticated applications. Three-dimensional visualizations of xenobiotic transport in fish and vapor transport in the rodent nose, physiological models of a parent chemical linked in series with one or more active metabolites, models describing biochemical interactions among xenobiotics, and more biologically realistic descriptions of tissues previously viewed as simple lumped compartments are just a few of the more sophisticated applications. Finally, physiologically based toxicokinetic models are now being linked to biologically based toxicodynamic models to simulate the entire exposure → dose → response paradigm that is basic to the science of toxicology.

BIOLOGICAL MONITORING

This final section considers some of the basic toxicokinetic principles and methods underlying the practice of biological monitoring, which over the past several decades has become an important

tool for assessment of environmental health risk, first in occupational exposure and more recently in general population exposure. Biological monitoring or biomonitoring is defined as the systematic sampling of body fluids, and at times body tissue, for the purpose of estimating an individual’s internal dose from exposure to chemicals in the workplace or assessing the range of internal exposure within a select population to environmental pollutants (Manno and Viau, 2010; Paustenbach and Galbraith, 2006). The advantages of biomonitoring over traditional environmental monitoring, such as ambient or personal air sampling or dermal dosimetry, include the accounting of other unanticipated routes of exposure, individual differences in toxicant absorption and disposition, and critical personal or lifestyle variables, such as body size and composition, workload that affects pulmonary ventilation, or cigarette smoking that could affect the metabolic status of an individual. Linking environmental exposure or dose to measurements of concentration of the parent chemical or its metabolite(s) in a biological sample is essentially an exercise in toxicokinetics.

Biomonitoring Reference

Although biomonitoring provides a measure of internal exposure, in the final analysis the data obtained must be relatable to a probable degree of health risk. Hence, for each chemical of concern a reference value must be established that corresponds to a threshold limit, below which a reasonable assurance of safety exist and above which significant risk to the exposed individual or population becomes likely.

In the occupational setting, the concept of Biological Exposure Index (BEI) has been established by the American Conference of Governmental Industrial Hygienists (ACGIH) since early 1980s. BEI for a given chemical exposure represented “. . . the level of the determinant most likely to be observed in the specimens collected from a worker with an internal dose equivalent to that arising solely from inhalation exposure at the TLV” (Morgan, 1997). Threshold limit values (TLVs) are the reference values recommended by ACGIH for airborne chemical concentrations in the workplace, below which nearly all workers may be exposed repeatedly over a working lifetime without known adverse health effects. BEIs for various industrial chemicals have been established through controlled exposure studies in a laboratory setting and/or simultaneous ambient exposure and biological sampling in the workplace. BEIs have also been estimated through the use of physiologically based modeling and simulations (Leung, 1992). The modeling approach is particularly attractive as it can readily simulate a wide variety of exposure condition, along with the ability to vary personal variables such as the level of physical exertion in a hypothetical worker. The impact of interindividual variability in physiological parameters on the BEI can also be evaluated using physiological models coupled with Monte Carlo simulations (Thomas *et al.*, 1996).

A similar referencing concept, referred to as the Biomonitoring Equivalents (BEs) approach, has also been proposed in population environmental exposure context. For BEs, available toxicokinetic data are used to convert an existing exposure guidance value (eg, reference doses or concentrations—RfDs or RfCs, minimal risk levels—MRLs, tolerable daily intakes—TDIs, or a unit cancer risk—UCR) into an equivalent concentration in a biological sample (Hays and Aylward, 2009). As in the case of BEIs, the conversion can be accomplished using classic or physiological models (Hays *et al.*, 2007).

It should be noted that in both settings, the measurement of parent chemical and/or its metabolite in a chosen biological

matrix serves as a biomarker for exposure, which in turn allows for health risk assessment based on generally accepted environmental exposure–risk data. It remains to be seen whether at some future time evidence providing a direct link between biological monitoring of internal dose and health risk will become available in both the occupational and general environmental settings.

Monitoring Strategy

The design of an optimal sampling strategy for biomonitoring is guided by three key considerations: (1) sampling matrix or site that includes blood, urine, exhaled breath, saliva, or hair; (2) choice of the determinant(s) (ie, parent compound and/or metabolites); and (3) sampling time relative to the exposure routine, especially when exposure is intermittent. In addition, normalization procedures have been proposed for some matrices to account for variation in individual physiological condition at the time of sampling. These issues are, in many cases, interrelated.

Decision on sampling time relative to the exposure pattern would be a straightforward matter if exposure was continuous and constant, in which case blood, urine, or other samples can be collected at any time after steady state is reached, that is, after 4 elimination half-lives have elapsed since the start of exposure. In reality, exposure is often episodic or intermittent, and in occupational setting exposure is dictated by the work shift.

Specific sampling times are recommended by ACGIH for each BEI. The commonly designated times include the end of shift, prior to start of a workday, the end of the last shift of the workweek, and the morning after returning from the weekend. The end-of-shift is a reasonable time to assess daily peak exposure for workplace chemicals that have reasonably short elimination half-lives (<6 hours) such that carryover from day to day is not significant (see Fig. 7-10). For chemicals that have elimination half-lives in the order of 12 to 24 hours (or longer), the end of the last shift of the week would be a better measure of peak exposure (see the 24-hour $T_{1/2}$ example in Fig. 7-10). For chemicals that have multiphasic washout kinetics (ie, kinetics conforming to a multicompartamental model), timing of sample collection relative to the end of exposure in the immediate after-shift period is critical when the early disposition half-life of the parent compound prevails and could be very short (eg, in the order of minutes). This renders the end-of-shift sampling imprecise because of the high degree of measurement variability, such is the case with blood or breath toluene samples taken at the end-of-shift (Morgan, 1997). One solution is to collect the sample just before the worker returns to the next shift on the day following or after a weekend, by which time washout kinetics has reached the terminal phase with an acceptably long half-life, so as to provide a more reproducible index. Finally, repeat sampling over days or weeks are often needed to firmly establish a representative exposure pattern in individual or groups of workers.

Systematically timed sampling is hardly feasible in a community population exposure study, where sampling is typically random, and exposure comes from diffuse sources and may not occur with any definable regularity. The only approach to overcome such shortcoming is to obtain samples at different times of a day to provide diurnal coverage, which introduces obvious logistical and cost challenges in a population surveillance program.

The choice of determinant or biomarker and the sampling matrix are interrelated. Monitoring of parent compound in blood or urine is preferred, particularly if toxicology of the chemical is attributed to the parent entity. In those instances where a metabolite is solely responsible for or contribute to the adverse

effects of exposure, monitoring of the active metabolite, along with the parent compound, would be a logical approach. Inactive metabolite(s) is(are) often times monitored as a surrogate marker in place of the parent toxicant due to its relative abundance, ease of analysis, and desirable toxicokinetic properties. For many chemicals, urinary excretion is not a principal route of elimination. At the same time, polar metabolites are often removed by renal excretion; hence, metabolites are present at high concentrations in urine. For example, hippuric acid (glycine conjugate of the major oxidation metabolite of toluene, benzoic acid) in urine is an accepted BEI for toluene exposure. For chemicals that have inherently short elimination half-life or effectively short washout half-life due to a prominent distribution phase, metabolite(s) with longer elimination half-life may be a more suitable biomarker (ie, being less sensitive to sampling time variation). It should, however, be noted that metabolite levels are governed by both its formation kinetics from parent chemical and its own elimination kinetics; hence, individual differences in metabolite elimination represents an additional sources of variability for metabolite monitoring. Hence, the kinetic advantage of metabolite monitoring is not predictable and must be assessed on a case-by-case basis.

It is not often appreciated that the observed level of a determinant for a chemical exposure is a function not only of current exposure, but also what happened some time before (Droz *et al.*, 1991). This is particular so when exposure is continuous or the interval between intermittent exposures is on the order of the chemical's elimination half-life (eg, an elimination $T_{1/2}$ of 24 hours or longer when exposure reoccurs on a daily basis). In other words, the elimination half-life of a biomarker or index compound dictates how far back in exposure history it reports. For example, exposure to the degreaser solvent, trichloroethylene results in urinary excretion of trichloroethanol (TCE) and trichloroacetic acid (TCA). The elimination $T_{1/2}$ of TCE is known to be 3 to 5 hours, whereas that of TCA ranges from 48 to 96 hours. Measuring these 2 metabolites in urine allows one to estimate the exposure of a worker to trichloroethylene during the current work shift with TEC and in the preceding workweek with TCA (Lowry, 1987). A corollary to this principle is the fact that short half-life biomarkers reflect more of the within day or day-to-day fluctuation in exposure, whereas daily fluctuation in exposure is dampened with long half-life biomarkers. Although the former cases may be viewed as undesirable because of variability in the measurement, it offers a better reflection of the oscillation in internal dose and particularly the transient peak exposures. The latter cases provide a less variable, time-averaged measure of exposure.

In addition to the above consideration of determinant abundance, the choice of sampling matrix is driven by ease of sampling and reliability in respect to inter- and intraindividual variations. The advantages and disadvantages for each of the common biological matrices are considered below.

Blood Blood concentration of determinant(s) is the most representative biological sample, because it should be in equilibrium with all tissue concentrations in the postdistribution phase (Fig. 7-2, right panels). This consideration extends to the relationship of blood concentration to other biological fluids (eg, urine and saliva); as such, concentration of determinant in all other biological fluids (eg, urine and saliva) indirectly reflects the concentration in blood. The major drawbacks of blood sampling are its invasive nature, subject acceptance, and the need for qualified medical personnel to perform blood draw. For environmental pollutants that are sequestered in adipose tissue, fat-soluble fraction of blood has been proposed as a

more practical substitute for adipose tissue sampling (Paustenbach and Galbraith, 2006).

Urine Ease in collection is often cited as a major advantage of sampling urine for biomonitoring; unfortunately, it belies the kinetic complexity involved in the analysis of urinary biomarker data. As mentioned earlier, monitoring of parent compound in urine only applies to a few chemicals that are excreted in significant amounts in urine; in most cases, metabolite(s) are measured in urine. Hence, the elimination kinetics of the marker metabolite need to be taken into account in data interpretation.

There are several types of urine collection: (1) timed collection over 24 hours or several hours; (2) spot urine usually from random collection; and (3) first morning specimen (Hill *et al.*, 1988). The timed urine collection should be performed according to the “double-void” protocol. Urine is collected after first emptying the bladder and then waiting until the next voiding. For extended collection, say over 24 hours, multiple in-between voids are collected and pooled with the final voiding at the end of the collection period. Timed urine collection affords a measure of the total amount of determinant excreted or the average excretion rate of the determinant over a defined time period. Spot urine, either from first morning sample or other times during the day, offers a measure of the urinary concentration of the determinant. The first morning sample has the advantage of being a concentrated overnight sample.

In order to appreciate the applicability and limitation of various urine collection methods in biomonitoring, a brief review of urinary excretion kinetics is in order. As was shown in the “Clearance” section, urinary excretion rate (dU_B/dt) of a biomarker or determinant is related to its concentration in blood or plasma concentration (C) by renal clearance (Cl_r).

$$\frac{dU_B}{dt} = Cl_r \cdot C \quad (7-29)$$

It should be noted that dU_B/dt represents an average urinary excretion over a relatively short collection interval; C is the blood or plasma concentration at the mid-time point. The differential form of Equation (7-29) can be integrated over an extended collection period, say 24 hours, to yield a relationship between the total amount excreted in the collection period ($U_{B,24}$) and the corresponding area under the blood or plasma concentration–time curve (AUC_{0-24} , an integral measure of exposure).

$$U_{B,24h} = Cl_r \cdot AUC_{0-24} \quad (7-30)$$

Hence, either excretion rate or cumulative excretion over a defined collection period of a urinary biomarker is the most appropriate index secondary to blood concentration measurement. Unfortunately timed urine collection is not widely adopted because of logistical difficulties in the occupational setting and cost issue in a population surveillance system.

Urinary excretion rate is in turn related to pooled urine concentration ($C_{UB,\Delta t}$) and urinary flow rate ($V_{\Delta t}/\Delta t$).

$$\frac{dU_B}{dt} = C_{UB,\Delta t} \cdot \left(\frac{V_{\Delta t}}{\Delta t} \right) \quad (7-31)$$

Urinary concentration as measured from spot collection offers convenience and flexibility; however, it has the distinct disadvantage of being influenced by urine flow rate, which varies greatly from time to time depending on the hydration state of the individual. Several methods have been proposed to adjust for variation in urine flow rate. Urinary creatinine is most often used to normalize

urinary concentration data. The following equation shows one such normalization (Garde *et al.*, 2011).

$$U_{B,24} = \left(\frac{C_{UB}}{C_{UCr}} \right) \cdot U_{Cr,24} \quad (7-32)$$

where C_{UB} and C_{UCr} are the respective biomarker and creatinine concentration in the spot urine collection, and $U_{Cr,24}$ is the daily urinary output of creatinine. This method assumes that blood concentration of biomarker is reasonably constant throughout the day (eg, during stable, continuous exposure or for a chemical with very long elimination half-life). The daily urinary output of creatinine is assumed to be constant between individual; alternately, it can also be adjusted according to individual variables that are known to affect creatinine production: body mass, age, and sex (Boeniger *et al.*, 1993).

An alternate, more commonly adopted normalization is to simply express the amount of biomarker in the spot urine collection per mmol of creatinine. This simple normalization is valid for spot urine collection if we assume creatinine excretion is constant throughout the day and reproducible from individual to individual, which are often not true. It is not surprising that validity of normalizing urinary biomarker to per mmol creatinine has been questioned (Boeniger *et al.*, 1993). Other normalization methods including adjustment to a standard urine flow rate, specific gravity, or osmolality have also been proposed (Hill *et al.*, 1988; Boeniger *et al.*, 1993).

The performance of these various normalization procedures has not been subject to rigorous comparison. It is doubtful any of them could offer a facile solution to the inherently difficult problem posed by spot urine collection in face of the known physiological variability in diuresis and creatinine production and excretion.

Breath Breath sampling is applicable to biomonitoring of volatile organic compounds (VOCs) including many industrial solvents. In some instances, it can be extended to volatile metabolites of non-volatile organic chemicals. Breath sampling offers the advantages of being noninvasive and can be performed rapidly, especially when repeated sampling at short time intervals is needed.

The utility of breath sample as a biomarker rests on the assumption that during exposure, VOC in the inspired air reaches the alveoli where it undergoes equilibrium exchange with the arterial blood, which in theory is predicted by the blood/air partition coefficient in vitro (see “Specialized Compartment: Lung”). This alveolar equilibrium assumption is valid for VOCs that have blood/air partition coefficients exceeding 10 (Kelman, 1982). Likewise, in the postexposure situation, unmetabolized volatile compound in mixed venous blood comes into equilibrium exchange with alveolar air, which is exhaled and sampled. Hence, breath sampling can provide an estimate of arterial blood concentration of VOCs based on their known blood/air partition coefficients (Wallace *et al.*, 1996). Partition coefficients for a large number of VOCs have been determined from in vitro studies; most have been validated by blood/breath ratios observed in controlled exposure studies in human subjects at ppm levels that are encountered in occupational settings. There are data to suggest that blood/breath ratio of some VOCs may increase at low ppb exposure levels typically present in the general environment (see example with benzene, Perbellini *et al.*, 1988).

Only 350 mL of the 500 mL inspired volume (tidal volume) actually ventilate the alveoli and undergo gaseous exchange. About 150 mL of inspired air is held in the anatomical dead space between the nose or mouth and the respiratory bronchioles. As a result, expired air when collected in total is a mixture of alveolar air and dead space air. If sampling is done during exposure, the dead space air has a VOC concentration of the last inspired air. If sampling is

done postexposure, the dead space air would have a near zero or background VOC concentration (Hill *et al.*, 1988). Therefore, total breath collection is not appropriate for biomonitoring. It has been suggested that mixed expired air concentration can be normalized to alveolar concentration using the observed CO₂ concentration (Wilson, 1986). However, this proposed method of normalization has not been sufficiently validated for VOCs of environmental interest.

Alveolar concentration is best measured by collecting the last part of an expiration (about 200 mL), that is, the end-expired or end-tidal air (Wilson, 1986; Hill *et al.*, 1988). Various devices for collection of end-expired air have been described (Wilson, 1986; Wilson and Monster, 1999). Breath holding and rebreathing techniques have also been proposed to promote equilibration of VOCs between alveolar air and blood in the pulmonary capillaries.

The major difficulty with breath as a biomonitoring matrix is achieving reproducible sampling. Success is critically dependent on strict adherence to a standardized breathing and collection protocol aimed at maintaining a consistent blood/breath ratio between occasions. It is well documented that variability is introduced when subjects breathe too quickly (hyperventilate) or breathe too slowly (hypoventilate) (Wilson, 1986; Hill *et al.*, 1988). Physical activity or workload, which affects ventilation–perfusion of the lungs, is known to alter end-expired air concentration of some VOCs (Wilson, 1986). Finally, standardization of volume and concentration from ambient condition during measurement to body temperature, pressure and water vapor saturation (Hill *et al.*, 1988), along with minor adjustment for contamination of dead space air in end-expired sample using CO₂ level have been proposed to improve the estimation of alveolar air concentration (Wallace *et al.*, 1996).

Saliva Saliva has drawn attention as a matrix for biomonitoring because of ease in its collection. Transfer of drugs and xenobiotics from blood into saliva occurs via diffusion across the salivary glands and is known to depend on the compound's lipophilicity and ionization (Caporossi *et al.*, 2010). Saliva contains a low concentration of proteins, mainly albumin derived from plasma and glycoproteins, which impart viscosity and protect the buccal epithelium. As a result, saliva/plasma ratio for neutral, nonprotein bound compounds is expected to be about one. Compounds that are highly bound to plasma proteins can have a saliva/plasma ratio well below one. Saliva pH is usually less than that of plasma; hence, in the absence of binding to plasma proteins, acidic compounds are predicted to have a saliva/plasma ratio less than one, whereas basic compounds could have saliva/plasma ratios greater than one due to pH trapping.

There are several ways to collect saliva. Most often whole saliva is collected, which is a complex mixture of oral fluids, including salivary gland secretions, gingival crevicular fluids, expectorated bronchial and nasal secretions, and even trace of serum and blood from oral bleeding. Whole saliva can be collected by spitting into a vial, wiping the oral cavity with a swab, or using commercially available collectors (eg, Salivette). Stimulants of salivary flow, such as citric acid and chewing gum, have been used to facilitate collection and increase the sample volume. Blood/saliva ratio could differ between stimulated and unstimulated collection condition; for example, change in saliva pH is associated with an increase in salivary flow, which may affect transfer of ionizable compounds into saliva. Direct collection of secretion from the parotid gland for therapeutic monitoring of drug level has been attempted using special collection devices.

In order to apply saliva sampling to biomonitoring, a consistent relationship between blood and saliva concentrations of the determinant is required. This has proven to be a problem for metals and industrial chemicals. For example, the use of saliva

for monitoring of Hg and Pb has been investigated in a number of studies. In many instances, Hg or Pb levels in saliva were below the limit of detection, or when detected poor correlations between concentrations in saliva and those in blood were observed. Use of saliva has also been evaluated for several pesticides, polychlorinated biphenyls (PCBs), polychlorinated dibenzo-*p*-dioxins (PCDDs), and industrial chemicals with mixed results (Esteban and Castaño, 2009; Caporossi *et al.*, 2010). More data will be required to assess the applicability of saliva in occupational and environmental biomonitoring.

Hair Hair is easy to collect, transport, and store. As hair grows out of the hair follicle, it carries with it a record of past exposure that stretch over weeks to many months. In fact, a temporal exposure pattern can be reconstructed by segmental analysis of a strand of hair. As such, hair is a unique biomonitor of cumulative exposure and is best suited for environmental pollutants that have long elimination half-lives in the order of days to weeks. The main disadvantages of hair as a biological matrix are the difficulty in differentiating external and internal exposure and the variable influence of hair pigmentation and hair care. Assay of biomarkers in the typical quantity of hair collected (50–200 mg) also requires highly sensitive analytical methodologies.

Hair has been used as a matrix for human biomonitoring of exposure to methylmercury for a number of years (Esteban and Castaño, 2009). A strong correlation exists between total Hg in hair and dietary intake of methylmercury, mainly through fish consumption. A predictable relation between hair Hg and blood Hg has also been documented; hence, hair Hg is an acceptable biomarker for the internal dose of Hg from methylmercury exposure. There are also adequate data to support the use of hair measurement as an indicator for occupational and environmental Pb exposure. In contrast, conflicting data exist on the relationship between hair Cd and body burden of Cd.

Much less is known in regards to hair as a biomonitor for organic pollutants (Appenzeller and Tsatsakis, 2012). Pesticides, particularly organochlorine pesticides, are the most investigated environmental pollutants in hair. Indeed hair sampling has been used to monitor workplace exposure to pesticides, as well as PCDDs, polychlorinated dibenzofurans (PCDFs), and coplanar PCBs; however, these reports offer mostly descriptive information (eg, percent of individuals being positive for presence of test pollutants in hair samples, levels of pollutants present in the hair) and have rarely evaluated the relationship of hair pollutant concentration to environmental levels or corresponding concentrations in blood and other biological matrices. Hence, the feasibility of hair sampling for occupational and environmental biomonitoring awaits further research.

Conclusions

The toxicokinetic principles that guide the design of biological monitoring have been established through more than two decades of occupational health research and are now being extended to assessment of population health risk from exposure to environmental pollutants. With the forthcoming of the wealth of environmental biomonitoring data that have recently been collected by public health agencies, such as the U.S. Centers for Disease Control and Prevention (CDC), much more will be learned in regards to biomonitoring strategy as it is applied to surveillance of low level environmental exposure in the various community settings. Even in the occupational health sector, more research is needed to improve the existing biomonitoring methods and technologies so that they become more cost-effective and in turn widen its adoption at the workplace.

Summary

OVERVIEW

Cancer is a disease characterized by mutation, modified gene expression, cell proliferation, and aberrant cell growth. It ranks as one of the leading causes of death in the world. In the United States, cancer ranks as the second leading cause of death, with over one million new cases of cancer diagnosed and more than 1.5 million Americans dying from cancer annually. Multiple causes of cancer have been established including infectious agents, radiation, and chemicals. Estimates suggest that 70% to 90% of all human cancers have a linkage to environmental, dietary, and behavioral factors (Fig. 8-1). Although our understanding of the biology of the progression from a normal cell to a malignant one has advanced considerably in the past several decades, many aspects of the cause, prevention, and treatment of human cancer in particular the influence of lifestyle remain unresolved.

HISTORICAL BACKGROUND

A strong historical foundation for the linkage of the induction of cancer by chemicals has been documented (Table 8-1). Several excellent reviews of the historical background of carcinogenesis and cancer research have been published (Creech, 2000; Diamandopoulos, 1996; Shimkin, 2008). Studies over the last three centuries on chemically induced cancer are marked initially by epidemiological observations followed by experimental studies involving animal carcinogenesis models.

In 1775, Percival Pott described a linkage between the increased occurrence of scrotal and nasal cancer among chimney sweeps and their occupation. Pott concluded that chimney soot was the causative agent for cancer induction in these individuals (Pott, 1775). Other investigators also recognized an association between exposure to chemicals and the induction of human cancer.

Figure 8-1. Proportions of human cancer deaths attributed to various factors. (Reproduced with permission from [no authors listed] Harvard reports on cancer prevention: causes of human cancer. Center for Cancer Prevention Harvard School of Public Health. *Cancer Causes and Control*. 1996;7 (Suppl 1):S3–S4, 1996.)

Thiersch (1875) described a relationship between sunlight exposure and skin cancer in humans. A linkage between an increased incidence of lung cancer and uranium mining was detected (Harting and Hesse, 1879). Butlin, in a follow-up of the Potts' observations, noted that scrotal cancer in chimney sweeps in the European

continent was relatively rare on the continent compared to that seen in England (Butlin, 1892). He attributed this difference to better hygiene practices by the European sweeps as well as to the use of younger boys in England, suggesting that age of exposure and the duration of exposure influence the formation of the cancer. In

Table 8-1

Historical Events in Chemically Induced Cancer

DATE	INVESTIGATOR(S)	CAUSATIVE AGENT
1775	Pott	Soot and chimney sweeps
1822	Ayrton	Arsenic containing metal
1875	Thiersch	Sunlight
1876	Manourriez	Coal tar
1879	Harting and Hesse	Lung cancer and uranium
1892	Butlin	Soot and chimney sweeps
1895	Rehn	Manufacture of aniline dyes
1902	Frieben	X-rays
1915	Davis	Pipe smokers and betel nut chewers
1915	Yamagiwa, Ichikawa, and Tsusui	Induction of skin cancer in rabbits and mice by coal tar
1920	Leitch and Seguina	Radium radiation
1928	Delore and Bergamo	Benzene
1930	Kennaway and Hieger	Tumor induction by dibenz[<i>a,h</i>]anthracene
1932	Stephens	Nickel
1932	Alwens	Chromium compounds
1933	Cook, Hewett, and Hieger	Isolation of the carcinogen benzo[<i>a</i>]pyrene from coal tar
1936	Yoshida and Kinoshita	Induction of liver cancer in rats by <i>o</i> -aminoazotoluene
1934	Wood and Gloyne	Arsenicals, beryllium, and asbestos
1934	Neitzel	Mineral oil mists and radiation
1936	Kawahata	Coal tar fumes
1938	Hueper, Wiley, and Wolfe	Induction of urinary cancer in dogs by 2-naphthylamine
1941	Berenblum, Rous, MacKenzie, and Kidd	Initiation and promotion stages in skin carcinogenesis with benzo[<i>a</i>]pyrene
1951	Miller and Miller	Carcinogen binding to cellular macromolecule
1956	Doll and Hill	Lung cancer and other causes of death in relation to smoking

1895, Rehn reported a linkage between the manufacturer of aniline dyes and the induction of bladder cancer in dye workers (Rehn, 1895). Due to the increase in demand for synthetic dyes in the 19th century, production of the aniline-based dyes increased, as did the development of skin and bladder cancer in exposed workers. The specific chemicals in the dyes related to the cause of skin and bladder cancer were later determined to be the aromatic compounds 2-naphthylamine and benzidine (Hueper *et al.*, 1938). Exposure of workers to metals, such as chromium (Alwens, 1938) and asbestos (Wood and Gloyne, 1934), was shown to be associated with an increased incidence of lung cancers in workers. Tobacco use and its linkage to lung cancer provide an excellent case study on the linkage between epidemiology and experimental carcinogenesis. As early as 1912, Adler noted an association between smokers and lung cancer (Spiro and Silvestri, 2005). Similarly, Lickint reported on the linkage between tobacco smoking and lung cancer in the 1920s and also associated the higher rate of lung cancer seen in males with tobacco smoking (Proctor, 2001). Subsequent investigations lead to the observation by Doll and colleagues, in a longitudinal epidemiology study, a direct cause and effect of smoking to lung cancer (Doll *et al.*, 2004).

Based on these human epidemiological observations, experimental investigations starting in the first half of the 20th century were performed to understand the biological mechanisms, nature of these chemical mixtures, and individual chemical compounds in the mixtures using animal models. Initial studies by Yamagiwa and co-workers examined the linkage between exposure to coal tar and its derivatives on cancer induction in humans by painting with coal tar on rabbit ears, which resulted in the formation of skin cancer (Yamagiwa *et al.*, 1915). Subsequently, Kennaway and Hieger purified dibenz(*a,h*)anthracene from this coal tar extract, and determined that dibenz(*a,h*)anthracene was at least one component of the coal tar mixture that was responsible for inducing skin cancer (Kennaway and Hieger, 1930). Cook and co-workers (1933) similarly extracted another polycyclic aromatic hydrocarbon (PAH), benzo(*a*)pyrene, from the coal tar and showed this to also function as a carcinogen in rodents. In similar approaches with aromatic amines, Hueper and colleagues reported that 2-naphthylamine induced bladder tumors in dogs (Hueper *et al.*, 1938) and Yoshida (1933) and Kinoshita (1936) found that feeding aminoazotoluene or aminoazobenzene to rodents induced liver cancer. James and Elizabeth Miller (and their students) in the last half of the 20th century established the role of chemical structure and metabolism in the “activation” of carcinogens to a macromolecular interactive form (Miller *et al.*, 1951; Miller and Miller, 1981; Miller *et al.*, 1983). Studies with the aromatic amine compounds in animal models correlated with the human epidemiological studies that had revealed an association between bladder cancer in humans and exposure to aniline dyes in the occupational setting and helped to define the specific chemicals in the dyes responsible for the cancer induction. Studies by investigators such as Harris and colleagues over the last 30 years have utilized the laboratory to examine the environmentally induced cancers reported in epidemiological finding, especially in the area of lung cancer and tobacco smoking (Greenblatt *et al.*, 1994). These epidemiological and experimental studies have shown a clear correlation between the induction of cancer in humans and rodents by chemical exposure.

An important historical event in the development of carcinogenesis testing was the development of a short-term bacterial-based mutagenesis bioassay in the early 1970s by Ames and colleagues. This Salmonella-based assay has become a stalwart in the early detection of mutagenic compounds that have the potential to be carcinogenic. A recent review of the historical aspects of the

development and use of the Salmonella assay has been published (Claxton *et al.*, 2010). The success of the Ames Salmonella Assay spurred the use of *in vitro* assays for mutagenicity in bacteria and mammalian cells as predictors of potential rodent and human carcinogens (Tennant *et al.*, 1987), culminating in the current genetic toxicity test battery (Eastmond *et al.*, 2009). As we move into the second decade of the 21st century, the onus to further develop high-throughput and shortened bioassays for carcinogen detection (cell or molecular biology based) has been identified, is ongoing (NAS, Tox 21 National Toxicology Program [NTP/NIEHS]; Toxicast [USEPA]), and represents new approaches based on our current understanding of the molecular steps in cancer-dependent pathways.

Definitions

An understanding of the cellular and molecular aspects of the cancer process requires an understanding of the scientific terms involved in defining and describing the pathology of neoplasia (Table 8-2). Neoplasia is defined as new growth or autonomous growth of tissue. A neoplastic lesion is referred to as a neoplasm. A neoplasm can be either benign or malignant. Both types of lesions are induced by chemical carcinogens. Benign neoplasms (eg, adenomas) are lesions characterized by expansive growth, frequently exhibiting slow rates of proliferation that do not invade surrounding tissue or other organs. Benign neoplasms can impair and damage the normal function of an organ through its growth impeding of blood flow. A malignant neoplasm (eg, a carcinoma) demonstrates invasive growth characteristics, capable of spreading not only through the organ of origin but via metastasis to other organs. Metastases are secondary growths derived from the cells of the primary malignant neoplasm.

The term tumor is a general term that is frequently used synonymously with a neoplastic lesion and describes a grossly visible lesion prior to a histopathological examination can confirm the exact type, grade, and stage of the neoplasm. In classifying neoplasms,

Table 8-2

Terminology

Neoplasia	New growth or autonomous growth of tissue
Neoplasm	The lesion resulting from the neoplasia
Benign	Lesions characterized by expansive growth, frequently exhibiting slow rates of proliferation that do not invade surrounding tissues
Malignant	Lesions demonstrating invasive growth, capable of metastases to other tissues and organs
Metastases	Secondary growths derived from a primary malignant neoplasm
Tumor	Lesion characterized by swelling or increase in size, may or may not be neoplastic
Cancer	Malignant neoplasm
Carcinogen	A physical or chemical agent that causes or induces neoplasia
Genotoxic	Carcinogens that interact with DNA resulting in mutation
Nongenotoxic	Carcinogens that modify gene expression but do not damage DNA

Table 8-3

Neoplasm Nomenclature

TISSUE OF ORIGIN	BENIGN NEOPLASM	MALIGNANT NEOPLASM
<i>Connective tissue</i>		
Bone	Osteoma	Osteosarcoma
Fibrous	Fibroma	Fibrosarcoma
Fat Lipid	Lipoma	Liposarcoma
<i>Blood cells and related cells</i>		
Hematopoietic cells		Leukemias
Lymphoid tissue		Lymphomas
<i>Muscle</i>		
Smooth	Leiomyoma	Leiomyosarcoma
Striated	Rhabdomyoma	Rhabdomyosarcoma
<i>Endothelium</i>		
	Hemangioma	Angiosarcoma
<i>Mesothelium</i>		
		Mesothelioma
<i>Epithelial</i>		
Squamous	Squamous cell papilloma	Squamous cell or carcinoma
Respiratory	Bronchial adenoma	Bronchogenic carcinoma
Renal epithelium	Renal tubular adenoma	Renal cell carcinoma
Liver cells	Liver cell adenoma	Hepatocellular carcinoma
Urinary epithelium	Transitional cell papilloma	Transitional cell carcinoma
Testicular epithelium		Seminoma
<i>Melanocytes</i>		
		Malignant melanoma

the nomenclature reflects both the tissue or cell of origin, and the characteristics of the type of tissue involved (Table 8-3). For benign neoplasms, the tissue of origin is frequently followed by the suffix “oma”; for example, a benign fibrous neoplasm would be termed *fibroma*, and a benign glandular epithelium termed an *adenoma*. Malignant neoplasms from epithelial origin are called *carcinomas* (from with the term cancer has evolved) while those derived from mesenchymal origin are referred to as *sarcoma*. Thus, a malignant neoplasm of fibrous tissue would be a *fibrosarcoma* while that derived from bone would be an *osteosarcoma*. Similarly, a malignant neoplasm from the liver would be a *hepatocellular carcinoma* while that derived from skin squamous epithelium is referred to as a *squamous cell carcinoma*. Preneoplastic lesions have also been observed in a number of target organs both animal models and humans, and reflect an early reversible lesion in neoplasm progression. The characterization and study of preneoplastic cells have led to further understanding of the process of cancer formation.

The term *cancer* describes a subset of neoplasia that represents malignant neoplasms. A *carcinogen* is an agent, chemical or physical, that causes or induces a cancer, although it is often also used to describe an agent that produces benign neoplastic lesions in rodent bioassays. In regulatory science this has been further defined as an agent whose administration to previously untreated animals leads to a statistically significant increased incidence of neoplasia of one of more histogenetic types as compared with the incidence seen in untreated control animals (Pitot, 1986). Thus,

the induction of either or both benign and malignant neoplasms by a chemical or physical agent is included in the definition of a carcinogen. Carcinogens can be chemicals, viruses, hormones, radiation, or solid materials. Carcinogens either produce new neoplastic growth in a tissue or organ or increase the incidence and/or multiplicity of background spontaneous neoplastic formation in the target tissue.

The process of carcinogenesis is a multistage and multistep process involving modification and mutation to a number of normal cellular processes. An extensive literature base exists to describe the changes that cells undergo during the formation of neoplasia. Characteristics of cancers and the biological processes involved have been extensively reviewed (Hanahan and Weinberg, 2011). For regulatory classification purposes carcinogens have frequently been divided simplistically into two major categories based on their general mode of action: genotoxic and nongenotoxic. Genotoxic carcinogens are those agents that interact with DNA to damage or change its structure. They are frequently mutagenic in a dose-responsive manner, and for regulatory purposes, they are classified as exhibiting low-dose linear patterns, which approximates a straight line at very low doses without a threshold and a lack of reversibility of effect upon removal of the agent.

Nongenotoxic carcinogens are the agents that do not directly interact with nuclear DNA. Nongenotoxic carcinogens may change gene expression, modify normal cell function, bind to or modify cellular receptors, and increase cell growth. These agents work through epigenetic mechanisms and change DNA expression without modifying or directly damaging its structure. Nongenotoxic chemicals create a situation in a cell or tissue that makes it more susceptible to DNA damage from other sources (natural or xenobiotic). Nongenotoxic agents for regulatory purposes exhibit a nonlinear, threshold, and reversible dose response pattern in their carcinogenicity. Common features of genotoxic and nongenotoxic carcinogens are shown in Table 8-4.

This knowledge has led to continued efforts, using both epidemiological information and experimental animal models, to assess chemical carcinogenicity of occupational, industrial, and environmental agents, to gain an understanding of the mechanisms of action of these agents, and to determine the relevance of human exposure to cancer risk.

MULTISTAGE CARCINOGENESIS

Extensive experimental studies with animal models and pathological evaluation of human cancers, have demonstrated that the carcinogenesis process involves a series of definable stages and steps

Table 8-4

Features of Genotoxic and Nongenotoxic Carcinogens

Genotoxic carcinogens

- Mutagenic
- Can be complete carcinogens
- Tumorigenicity is dose responsive
- No theoretical threshold

Nongenotoxic carcinogens

- Nonmutagenic
- Threshold, reversible
- Tumorigenicity is dose responsive
- May function at tumor promotion stage
- No direct DNA damage
- Species, strain, tissue specificity

Figure 8-2. Multistage model carcinogenesis.

(Shih *et al.*, 2001; Osada and Takahashi, 2002). Operationally, three defined stages, initiation, promotion, and progression have been identified in rodent studies (initially in skin and liver tumors models) (Fig. 8-2). These steps follow a temporal sequence of events demonstrable by histopathology and observed in a wide variety of target tissues. The defining characteristics of each of these stages are outlined in Table 8-5.

Initiation

The first stage of the cancer process involves initiation, a process that is defined as a stable, heritable change. This stage is a rapid, irreversible process that results in a carcinogen-induced mutational event. Chemical and physical agents that function at this stage are referred to as initiators or initiating agents. Initiating agents lead to genetic changes including mutations and deletions. Chemical carcinogens that covalently bind to DNA and form adducts that result in mutations are initiating agents. Included among chemicals classified as initiating carcinogens are compounds such as polycyclic hydrocarbons and nitrosamines,

biological agents, certain viruses, and physical agents such as x-rays and ultraviolet (UV) light. Most chemical carcinogens that function at the initiation stage of the cancer process are indirect-acting genotoxic compounds that require metabolic activation in the target cell to produce the DNA-damaging event. For these compounds, the chemical must be taken into the target site and metabolized (in the case of an indirect genotoxic carcinogen). The ultimate form of the carcinogen is then able to bind to nuclear DNA, resulting in adduct formation. The initiating event becomes “fixed” when the DNA adducts or other damage to DNA is not correctly repaired or is incompletely repaired prior to DNA synthesis. This event can lead to inappropriate base pairing and formation of a mutation.

Initiation by itself does not appear to be sufficient for neoplastic formation. Once initiated cells are formed, their fate has multiple potential outcomes: (1) the initiated cell can remain in a static nondividing state through influences by growth control either via normal surrounding cells or through endocrine influence; (2) the initiated cell may possess mutations incompatible with viability or normal function and be deleted through apoptotic mechanisms; or (3) the cell, through stimuli such as intrinsic factors or from chemical exposure, may undergo cell division resulting in the growth in the proliferation of the initiated cell. Besides the production of an initiated cell through carcinogen binding and misrepair, additional evidence has come forth showing that induction of continual stress, resulting in continual cell proliferation, can also produce new mutated, initiated cells (Matthews *et al.*, 2009; Johnstone and Baylin, 2010). Therefore, modification of cell signaling and gene expression (while usually ascribed to the tumor promotion process and as an epigenic pathway [see below]) may indirectly through sustained cell proliferation also result in the formation of mutations (Lewandowska and Bartoszek, 2011). In some instances, typically following relatively high doses and/or repeated exposure to the genotoxic carcinogen, a chemical carcinogen may function as a complete carcinogen, that is, it is capable of progressing through all stages of the cancer process.

Promotion

The second stage of the carcinogenesis process, derived from either endogenous or exogenous stimuli of cell growth, involves the selective clonal expansion of initiated cells to produce a pre-neoplastic lesion. This is referred to as the promotion stage of the carcinogenesis process. Both exogenous and endogenous agents that function at this stage are referred to as tumor promoters. Tumor promoters are not mutagenic and generally are not able to induce tumors by themselves; rather they act through several mechanisms involving gene expression changes that result in sustained cell proliferation either through increases in cell proliferation and/or the inhibition of apoptosis. This stage involves the modulation of gene expression through receptor or non-receptor-mediated processes. Nongenotoxic carcinogens frequently function at

Table 8-5

Characteristics of the Stages of Carcinogenesis Process

Initiation

- DNA modification
- Mutation
- Genotoxic
- One cell division necessary to lock-in mutation
- Modification is not enough to produce cancer
- Nonreversible
- Single treatment can induce mutation

Promotion

- No direct DNA modification
- Nongenotoxic
- No direct mutation
- Multiple cell divisions necessary
- Clonal expansion of the initiated cell population
- Increase in cell proliferation or decrease in cell death (apoptosis)
- Reversible
- Multiple treatments (prolonged treatment) necessary
- Threshold

Progression

- DNA modification
- Genotoxic event
- Mutation, chromosome disarrangement
- Changes from preneoplasia to neoplasia benign/malignant
- Irreversible
- Number of treatments needed with compound unknown (may require only single treatment)

the tumor promotion stage. The growth of preneoplastic lesions requires repeated applications or continuous exposure to tumor-promoting compounds. Although initial exposure to tumor promoters may result in an increase in cell proliferation and/or DNA synthesis in all tissues of the organ, this is usually a transient effect on the normal cells and with repeated applications of the tumor promoter only the initiated cells continue to clonally expand and divide (Fig. 8-2). Promotion is a reversible phenomenon whereby upon removal of the promotional agent, the focal cells may return back to the initiated cell. In addition, these agents demonstrate a well-documented threshold for their effects—below a certain dose or frequency of application; tumor promoters are unable to induce cell proliferation. Multiple chemical compounds as well as physical agents have been linked to the tumor promotion stage of the cancer process. Tumor promoters in general show organ-specific effects, for example, a tumor promoter of the liver, such as phenobarbital, will not function as a tumor promoter in the skin or other tissues.

Progression

The final stage of the carcinogenesis process, progression, involves the conversion of the benign preneoplastic lesions into a neoplastic cancer. In this stage, due to increase in DNA synthesis in cell proliferation in the preneoplastic lesions, additional genotoxic events may occur resulting in additional DNA damage including chromosomal damage such as aberrations and translocations. These events result in the transfer from preneoplastic, clonally derived cell populations into neoplastic cell populations. Cells accumulate a variety of mutations and epigenetic changes that cause them to outgrow the surrounding cells and to attract all of the necessary nutrients via angiogenesis. The tumor microenvironment has been also shown to be an important component of this process and the presence of “normal” cells and stroma within the lesion is critical for the neoplastic cells to survive and propagate. During the progression phase of the process the clonal nature of the neoplastic lesion is typically lost with a polyclonal appearance of cells within the lesion. Agents that impact on the progression stage are usually genotoxic agents although the acquisition of additional mutagenic events may occur through the continual stimulation of cell proliferation. By definition, the progression stage is an irreversible stage in that neoplasm formation, whether benign or malignant, occurs. With the formation of neoplasia, an autonomous growth and/or lack of growth control is achieved. Spontaneous progression can occur from spontaneous karyotypic changes that occur in mitotically active initiated cells during promotion. An accumulation of nonrandom chromosomal aberrations and karyotypic instability are hallmarks of progression. As such, chemicals that function as progressor agents are many times clastogenic and are capable of causing chromosomal abnormalities. Complete carcinogens have the ability to produce initiation, promotion and progression and hence by definition have genotoxic properties. In addition, a number of model systems are available to test for carcinogenicity and/or to study the multistep mechanisms involved in chemical carcinogenesis. The models are described in a later section of this chapter.

MECHANISMS OF ACTION OF CHEMICAL CARCINOGENS

The formation of a neoplasm is a multistage, multistep process that involves the ultimate release of the neoplastic cells from normal growth control processes and creating a tumor microenvironment.

Table 8-6

Hallmarks of Cancer

Eight properties of neoplastic cells that impart and contribute to their ability to independently growth and eventually metastasize

1. sustaining cell proliferation
2. resisting cell death (apoptosis)
3. inducing angiogenesis
4. enabling replicative immortality
5. activating invasion and metastasis
6. evading growth suppressors
7. reprogramming of energy metabolism
8. evading immune destruction

SOURCE: Data from Hanahan and Weinberg [2011].

In a highly regarded review, Hanahan and Weinberg (2000) initially defined the major characteristics of a neoplasm as it progresses into a malignant state. This review has recently been updated (Hanahan and Weinberg, 2011). These authors have proposed eight “hallmarks of cancer” that involve modifications to the homeostasis of normal cells imparting the growth and metastatic properties seen in the development of a neoplastic cell. These eight properties include (1) sustaining cell proliferation, (2) resisting cell death (apoptosis), (3) inducing angiogenesis, (4) enabling replicative immortality, (5) activating invasion and metastasis, (6) evading growth suppressors, (7) reprogramming of energy metabolism, and (8) evading immune destruction (Table 8-6). An important concept from this review is the fact that tumors are not just a collection of clonal neoplastic cells but a complex tissue with multiple cell populations and interact with one another and function as a unique tissue. This tumor microenvironment involves the recruitment of normal stromal and inflammatory cells that contribute to the growth the development of the neoplasm.

Although our understanding of the cancer process has expanded exponentially in the past several decades as is illustrated by the “hallmarks-of-cancer” concept, in its minimalist form two major processes are needed with regard to the induction of neoplasia by chemical agents: a mutational event and a selective proliferation of the mutated cell to form a neoplasm. Based on this supposition, chemicals that induce cancer have been classified into one of two broad categories (as noted above)—genotoxic or DNA-reactive agents, and nongenotoxic or epigenetic agents. This is admittedly a very simplistic approach to the complexities of the cancer process (as illustrated by the Hanahan and Weinberg’s review [2011]); however, for the purposes of regulatory processes and risk assessment this categorization has for the most part continued.

Genotoxic/DNA-Reactive Compounds

Genotoxic compounds interact with nuclear DNA of a target cell producing unrepaired DNA damage that is inherited in subsequent daughter cells. Experimental and epidemiological observations made in the middle of the 20th century identified a number of chemicals that could cause cancer in humans or experimental animals. Coal tar carcinogens including benzo(*a*)pyrene, pesticides such as 2-acetylaminofluorine and azo dyes such as diaminobenzamide were among the first chemical carcinogens to be studied. DNA-reactive carcinogens can be further subdivided according to whether they are active in their parent form (ie, direct-acting: agents that can directly bind to DNA without being metabolized) and those that require metabolic activation (ie, indirect-acting carcinogens: compounds that require metabolism in order to react with

Table 8-7

Examples of Genotoxic Carcinogens

A. Direct-acting carcinogens

Nitrogen or sulfur mustards
 Propane sulfone
 Methyl methane sulfonate
 Ethyleneimine
 B-Propiolactone
 1,2,3,4-Diepoxybutane
 Dimethyl sulfate
 Bis-(Chloromethyl) ether
 Dimethylcarbamyl chloride

B. Chemicals requiring activation (indirect-acting carcinogens)

Polycyclic aromatic hydrocarbons and heterocyclic aromatics
 Aromatic amines
N-Nitrosoamines
 Azo dyes
 Hydrazines
 Cycasin
 Safrole
 Chlorinated hydrocarbons
 Aflatoxin
 Mycotoxin
 Pyrrolizidine alkaloids
 Bracken fern
 Carbamates

Figure 8-3. Structures of reactive electrophiles.

Indirect-Acting Genotoxic Carcinogens An important discovery in the understanding of chemical carcinogenesis came from the investigations of the Millers who established that many carcinogens are not intrinsically carcinogenic, but require metabolic activation to be carcinogenic. They demonstrated that azo dyes covalently bind to proteins in liver, leading to the conclusion that carcinogens may bind to proteins that are critical for cell growth control (Miller and Miller, 1947). Work with benzo(*a*)pyrene showed covalent binding of benzo(*a*)pyrene or the metabolites of benzo(*a*)pyrene in rodents (Miller *et al.*, 1951). Subsequent investigations with other indirect-acting genotoxic carcinogens by other investigators confirmed that metabolism of the parent compound was necessary to produce a metabolite (activation) that was able to interact with DNA (Miller, 1970).

It has since been shown that the majority of DNA-reactive carcinogens are found as parent compounds, or procarcinogens. Procarcinogens are stable chemicals that require subsequent metabolism to be carcinogenic (Conney, 1982; Miller and Miller, 1981; Miller *et al.*, 1983; Weisburger and Williams, 1981 in Becker, 1982). The terms procarcinogen, proximate carcinogen, and ultimate carcinogen have been coined to define the parent compound (procarcinogen) and its metabolite form, either intermediate (proximate carcinogen) or final (ultimate carcinogen) that reacts with DNA (Fig. 8-4). The ultimate form of the carcinogen is most likely the chemical species that results in mutation and neoplastic transformation. The ultimate form of certain carcinogenic chemicals is not known, whereas for other chemicals there may be more than one ultimate carcinogenic metabolite depending on the metabolic pathway followed. It is important to note that besides activation of the procarcinogen to a DNA-reactive form, detoxification pathways may also occur inactivating the carcinogen.

Indirect-acting genotoxic carcinogens usually produce their neoplastic effects, not at the site of exposure (as seen with direct-acting genotoxic carcinogens) but at the target tissue where the metabolic activation of the chemical occurs. Indirect-acting genotoxic carcinogens include the polycyclic PAHs, nitrosamines, aromatic amines, and aflatoxin B1. Fig. 8-4 shows the parent

DNA). Examples of direct-acting and indirect-acting carcinogens are listed in Table 8-7.

Direct-Acting (Activation-Independent) Carcinogens A class of carcinogens that do not require metabolic activation or modification to induce cancer, are termed direct-acting or activation-independent carcinogens. These chemicals are also defined as ultimate carcinogens. Examination of the chemical structure of these chemicals reveals that they are highly reactive electrophilic molecules that can interact with and bind to nucleophiles such as cellular macromolecules including DNA. Some common electrophilic species in these groups are shown in Fig. 8-3. Generally these chemicals containing these moieties frequently cause tumor formation at the site of chemical exposure.

Direct-acting carcinogens include epoxides, imines, alkyl and sulfate esters, and mustard gasses (Fox and Scott, 1980; Sontag, 1981). Direct-acting electrophilic carcinogenic chemicals typically test positive in the Ames test without additional bioactivation with a liver metabolic fraction. The relative carcinogenic strength of direct-acting carcinogens depends in part on the relative rates of interaction between the chemical and genomic DNA, as well as competing reactions with the chemical and other cellular nucleophiles. The relative carcinogenic activity of direct-acting carcinogens is dependent upon such competing reactions and also on detoxification reactions. Chemical stability, transport, and membrane permeability determine the carcinogenic activity of the chemical. Direct-acting carcinogens are typically carcinogenic at multiple sites and in all species examined. A number of direct-acting alkylating agents, including a number of chemotherapeutic chemicals, are carcinogenic in humans (Marselos and Vainio, 1991).

(procarcinogen) and metabolites for several representative indirect-acting genotoxic carcinogens.

Mutagenesis

The reaction of a carcinogen with genomic DNA either directly or indirectly may result in DNA adduct formation or DNA damage, and frequently produces a mutation. Several mechanisms of mutagenesis are known to occur. Modification of DNA by electrophilic

carcinogens can lead to a number of products. These events are dependent upon when in the cell cycle the adducts are formed, where the adducts are formed, and, the type of repair process used in response to the damage.

Transitions are a substitution of one pyrimidine by the other or one purine by the other (changes within a chemical class), whereas a transversion occurs when a purine is replaced by a pyrimidine or a pyrimidine is replaced by a purine (changes across a chemical

class). Carcinogens can induce transitions and transversions several ways. In one scenario, when adducts (or apurinic or apyrimidinic sites) are encountered by the DNA replication processes, they may be misread. The polymerase may preferentially insert an adenine (A) in response to a noninformative site. Thus, the daughter strand of an A, C, G, or T adduct will have an adenine (A) and this change is fixed (mutation) and resistant to subsequent DNA repair. A second outcome, a shift in the reading frame (resulting in a frame shift mutation) may also result from carcinogen–DNA adducts formation. Most frame shift mutations are deletions and occur more frequently when the carcinogen–DNA adduct is formed on a nucleotide. In a third scenario, DNA strand breaks can also result from carcinogen–DNA adducts. These may arise either as a result of excision repair mechanisms that are incomplete during DNA replication or via direct alkylation of the phosphodiester backbone leading to backbone cleavage. Strand scission can lead to double-strand breaks, recombination, or loss of heterozygosity.

Damage by Alkylating Electrophiles

As noted above, most chemical carcinogens require metabolic activation to exert a carcinogenic effect. The ultimate carcinogenic forms of these chemicals are frequently strong electrophiles (Fig. 8-3) that can readily form covalent adducts with nucleophilic targets. Because of their unpaired electrons, S, O, and N: atoms are nucleophilic targets of many electrophiles. The extent of adducts formed is limited by the structure of DNA where bulky electrophilic chemicals can bind, and size of the ultimate carcinogenic form. In general, the stronger electrophiles display a greater range of nucleophilic targets (ie, they can attack weak and strong nucleophiles), whereas weak electrophiles are only capable of alkylating strong nucleophiles (eg, S: atoms in amino acids). In addition, the metabolic capability of a target cell will dictate the extent and types of electrophiles generated from the procarcinogenic parent.

An important and abundant source of nucleophiles is contained not only in the DNA bases, but also in the phosphodiester backbone (Fig. 8-5). Although carcinogen–DNA adducts may be formed at all sites in DNA, the most common sites of alkylation include the N^7 of guanine, the N^3 of adenine, the N^1 of adenine, the N^3 of guanine, and the O^6 of guanine. Alkylations of phosphate may also occur at a high frequency. Selective examples of carcinogen interactions with proteins and nucleic acids are shown in Fig. 8-6. Different electrophilic carcinogens will often display different preferences for nucleophilic sites in DNA and different spectra of damage. Dimethylnitrosamine and diethylnitrosamine, for example, are metabolized by P450 oxidation to yield a methyl carbonium ion (CH_3^+) and an ethyl carbonium ion (CH_3CH_2^+), respectively. Despite the structural similarities of the ultimate electrophiles, they display significant differences in alkylation profiles (Pegg, 1984). The relative proportions of methylated bases present in DNA following reaction with carcinogen-methylating agents are shown in Table 8-8 (Pegg, 1984). The predominant adduct formed following exposure to methylating agents such as methylmethane sulfonate is 7-methylguanine. In contrast, ethylating agents produce adducts predominately in the phosphate backbone of DNA. The carcinogenic potential of the type of adducts formed is often debated; some believe that O^6 -alkylguanine is the most carcinogenic adduct, whereas others report that O^4 -alkylthymine is more important in the carcinogenic process due to its persistence relative to other adducts (Pegg, 1984; Swenberg *et al.*, 1984).

Another common modification to DNA is the hydroxylation of DNA bases. Oxidative DNA adducts have been identified in all four DNA bases (Fig. 8-7); however, 8-hydroxyguanine is among

Figure 8-5. Examples of cellular nucleophiles and sites of possible adduct formation.

the most prevalent oxidative DNA adduct (Floyd, 1990). The source of oxidative DNA damage is typically formed from free radical reactions that occur endogenously in the cell or from exogenous sources (Klaunig and Kamendulis, 2004; Floyd, 1990; Ames and Shigenaga, 1993). Although a relatively large amount of oxidative DNA adducts have been proposed to be formed per day, repair mechanisms exist that maintain the cellular level at a low rate and keep endogenous mutations to a relatively low level. The role of oxidative damage and oxidative stress is discussed in greater detail later in this chapter.

Methylation of deoxycytidine residues is a well-studied DNA adduct. This reaction occurs by the transfer of a methyl group from *S*-adenosylmethionine by DNA methyltransferases (Holliday, 1989). Methylation of DNA results in heritable expression or repression of genes, with hypomethylation associated with active transcription of genes, whereas hypermethylated genes tend to be rarely transcribed. Chemical carcinogens may inhibit DNA methylation by several mechanisms including forming covalent adducts, single-strand breaks in the DNA, alteration of methionine pools, and inactivation of the DNA methyltransferase responsible for methylation (Riggs and Jones, 1983). The importance of DNA methylation in chemical carcinogenesis is discussed further later in this chapter.

Although a large number of adducts can be formed following exposure to chemicals, whether a particular DNA adduct will result in mutation and participate in the carcinogenesis process

Figure 8-6. Select structures of protein- and nucleic acid-bound forms of certain chemical carcinogens.

is dependent in part on the persistence of the adduct through the process of DNA replication, which is also in part dependent upon DNA repair.

DNA Repair

Following the formation of a carcinogen–DNA adduct, the persistence of the adduct is a major determinant of the outcome. This persistence depends on the ability of the cell to repair the altered DNA. The detection of unique DNA adducts has proven to be important in understanding the mechanism of action of specific carcinogens and has been correlated with carcinogenesis (Goth and Rajewsky, 1974; Swenberg *et al.*, 1985; Kadlubar *et al.*, 1981; Becker and Shank, 1985). However, the presence of a DNA adduct is not sufficient

for the carcinogenesis process to proceed. The relative rates or persistence of particular DNA adducts may be an important determinant of carcinogenicity, for example, *O*⁴-ethylthymine is relatively stable in DNA whereas *O*⁶-ethylguanine does not persist in DNA after continuous exposure to diethylnitrosamine (Swenberg *et al.*, 1984). The persistence of DNA adducts of *trans*-4-aminostilbene does not correlate with organ carcinogenicity and/or tissue susceptibility. Although the liver and kidney exhibited the greatest burden and persistence of the adduct and the Zymbals gland showed the least amount of DNA adducts, the latter tissue was more susceptible to carcinogenesis by this chemical (Neumann, 1983). As such, differences in susceptibility to carcinogenesis are likely the result of a number of factors, including DNA replication within a tissue and repair of a DNA adduct.

Table 8-8

Relative Proportions of Methylated Bases Present in DNA After Reaction With Carcinogenic Alkylating Agents

	PERCENT OF TOTAL ALKYLATION BY	
	DIMETHYL-NITROSAMINE, N-METHYL-N-NITROSOUREA, OR 1,2-DIMETHYL-HYDAZINE	DIETHYL-NITROSAMINE OR N-ETHYL-N-NITROSOUREA
1-Alkyladenine	0.7	0.3
3-Alkyladenine	8	4
7-Alkyladenine	1.5	0.4
3-Alkylguanine	0.8	0.6
7-Alkylguanine	68	12
O ⁶ -Alkylguanine	7.5	8
3-Alkylcytosine	0.5	0.2

3-Alkylthymine	0.3	0.8
O ² -Alkylthymine	0.1	7
O ⁴ -Alkylthymine	0.1–0.7	1–4
Alkylphosphates	12	53

The quantitation of covalent DNA adducts in tissues has been used to demonstrate exposure of humans to carcinogenic chemicals and to assess the relative risk from exposure to carcinogenic chemicals. For example, DNA adducts of carcinogenic PAHs have been demonstrated at relatively high levels in tissues and blood of

Figure 8-7. Structures of selected oxidative bases.

smokers and foundry workers compared with nonexposed individuals (Perera *et al.*, 1991). In addition, DNA adducts of aflatoxin B1 were seen in samples of human placenta and cord blood in individuals in Taiwan, an area that demonstrates a high incidence of liver cancer (Hsieh and Hsieh, 1993). The presence of macromolecular carcinogen adducts may be important to their mechanism of carcinogenicity, the presence and persistence of the adducts is only one factor in the process of cancer development.

Experimental and epidemiological evidence indicates that the development of cancer following exposure to chemical carcinogens is a relatively rare event. This can be explained by the ability of a cell to recognize and repair DNA. The DNA region containing the adduct is removed and a new patch of DNA is synthesized, using the opposite intact strand as a template. The new DNA segment is then spliced into the DNA molecule in place of the defective one. To be effective in restoring a cell to normal, repair of DNA must occur prior to cell division; if repair is not complete prior to replication, the presence of the adducts can give rise to mispairing of bases and other genetic effects such as rearrangements and translocations of DNA segments. Thus, a chemical that alters the repair process or the rate of cell division can itself affect the frequency of mutation and neoplastic transformation.

DNA Repair Mechanisms

Although cells possess mechanisms to repair many types of DNA damage, these are not always completely effective, and residual DNA damage can lead to the insertion of an incorrect base during DNA replication, followed by transcription and translation of the mutated templates, ultimately leading to the synthesis of altered protein. Mutations in an oncogene, tumor-suppressor gene or gene that controls the cell cycle, can result in a clonal cell population with a proliferative or survival advantage. The development of a tumor requires many such events, occurring over a long period of time, and for this reason human cancer induction often takes place within the context of chronic exposure to chemical carcinogens.

A number of structural alterations may occur in DNA as a result of interaction with reactive chemicals or radiation, and the more frequent types of damage are depicted in Fig. 8-8. The reaction of chemical species with DNA can produce adducts within the bases, sugar and phosphate backbone of DNA. In addition, bifunctional alkylating agents (such as mustards) may cause DNA cross-linking between two opposing bases. Other structural changes such as pyrimidine dimer formation are specific for exposure to UV light whereas double-stranded breaks in DNA are more commonly associated with ionizing radiation. A variety of mechanisms have evolved to effectively remediate and repair DNA damage. The more common types of DNA repair mechanisms seen in mammals are listed in Table 8-9.

In addition to the proofreading activity of DNA polymerases that can correct miscopied bases during replication, cells have several mechanisms for repairing DNA damage. Repair of DNA damage does not always occur prior to cell replication, and, in addition, repair of DNA damage by some chemicals is relatively inefficient, as such, exposure to chemicals that cause DNA damage can increase the probability of acquiring mutations that ultimately lead to cancer development.

Mismatch Repair of Single-Base Mispairs Spontaneous mutations may occur through normal cellular DNA replication mistakes. Many spontaneous mutations are point mutations, a change in a single base pair in the DNA sequence, or a small insertion or deletion or a frame shift mutation of some modest size. The issue for mismatch repair is determining which is the normal DNA

Figure 8-8. Schematic representation of chemical and radiation-induced lesions in DNA.

and which is the damaged DNA strand, and, therefore, repairing the mutated strand such that the correct base pairs are restored. Depurination is a fairly common occurrence and spontaneous event in mammals, and results in the formation of apurinic sites. If these lesions are left unrepaired, mutations are generated during DNA replication as DNA synthetic machinery is unable to determine the appropriate base with which to pair. All mammalian cells possess apurinic endonucleases that function to cut DNA near apurinic sites. The cut is then extended by exonucleases, and the resulting gap repaired by DNA polymerase and ligase.

Excision Repair DNA regions containing chemically modified bases, or DNA chemical adducts, are typically repaired by

excision repair processes. DNA adducts cause a distortion in the normal shape of DNA. Proteins that slide along the surface of a double-stranded DNA molecule recognize the irregularities in the shape of the double helix, and affect the repair of the lesion. DNA lesions that are repaired by excision repair processes include thymine–thymine dimers, produced following exposure to UV light, dimers that interfere with both replication and transcription of DNA. The repair of DNA regions containing bases altered by the attachment of large chemical adducts such as benzo(*a*)pyrene are also effectively repaired by excision repair processes (Fig. 8-9).

End-Joining Repair of Nonhomologous DNA A cell that has double-strand breaks can be repaired by joining the free DNA ends. The joining of broken ends from different chromosomes, however, will lead to the translocation of DNA pieces from one chromosome to another, translocations that have the potential to enable abnormal cell growth by placing a proto-oncogene next to, and, therefore, under the control of another gene promoter. Double-strand breaks can be caused by ionizing radiation and drugs such as anticancer drugs. Double-strand breaks are correctly repaired only when the free ends of DNA rejoin exactly. The repair of double-stranded DNA is therefore confounded by the absence of single-stranded regions that can signal the correct base pairing during the rejoining process. Homologous recombination is one of two mechanisms responsible for the repair of double-strand breaks. In this process,

Table 8-9

DNA Repair Pathways

1. Direct reversal of DNA damage
2. Excision repair systems
 - Base excision repair
 - Nucleotide excision repair
 - Mismatch repair
3. Postreplicational repair (recombination repair)
4. Nonhomologous end-joining (NHEJ): double-strand break repair

the double-strand break on one chromosome is repaired using the information on the homologous, intact chromosome.

The predominant mechanism for double-stranded DNA repair in multicellular organisms is nonhomologous repair and involves the rejoining the ends of the two DNA molecules. Although this process yields a continuous double-stranded molecule, several base pairs are lost at the joining point. This type of deletion may produce a possibly mutagenic coding change.

Classes of Genotoxic Carcinogens

Polyaromatic Hydrocarbons PAHs are found at high levels in charcoal-broiled foods, cigarette smoke, and in diesel exhaust. Representative chemicals belonging to this class are shown in Fig. 8-10A. A recent review of the causes of human cancer (*103 human carcinogens*) also lists those PAHs linked to human cancer by the International Agency for Research in Cancer

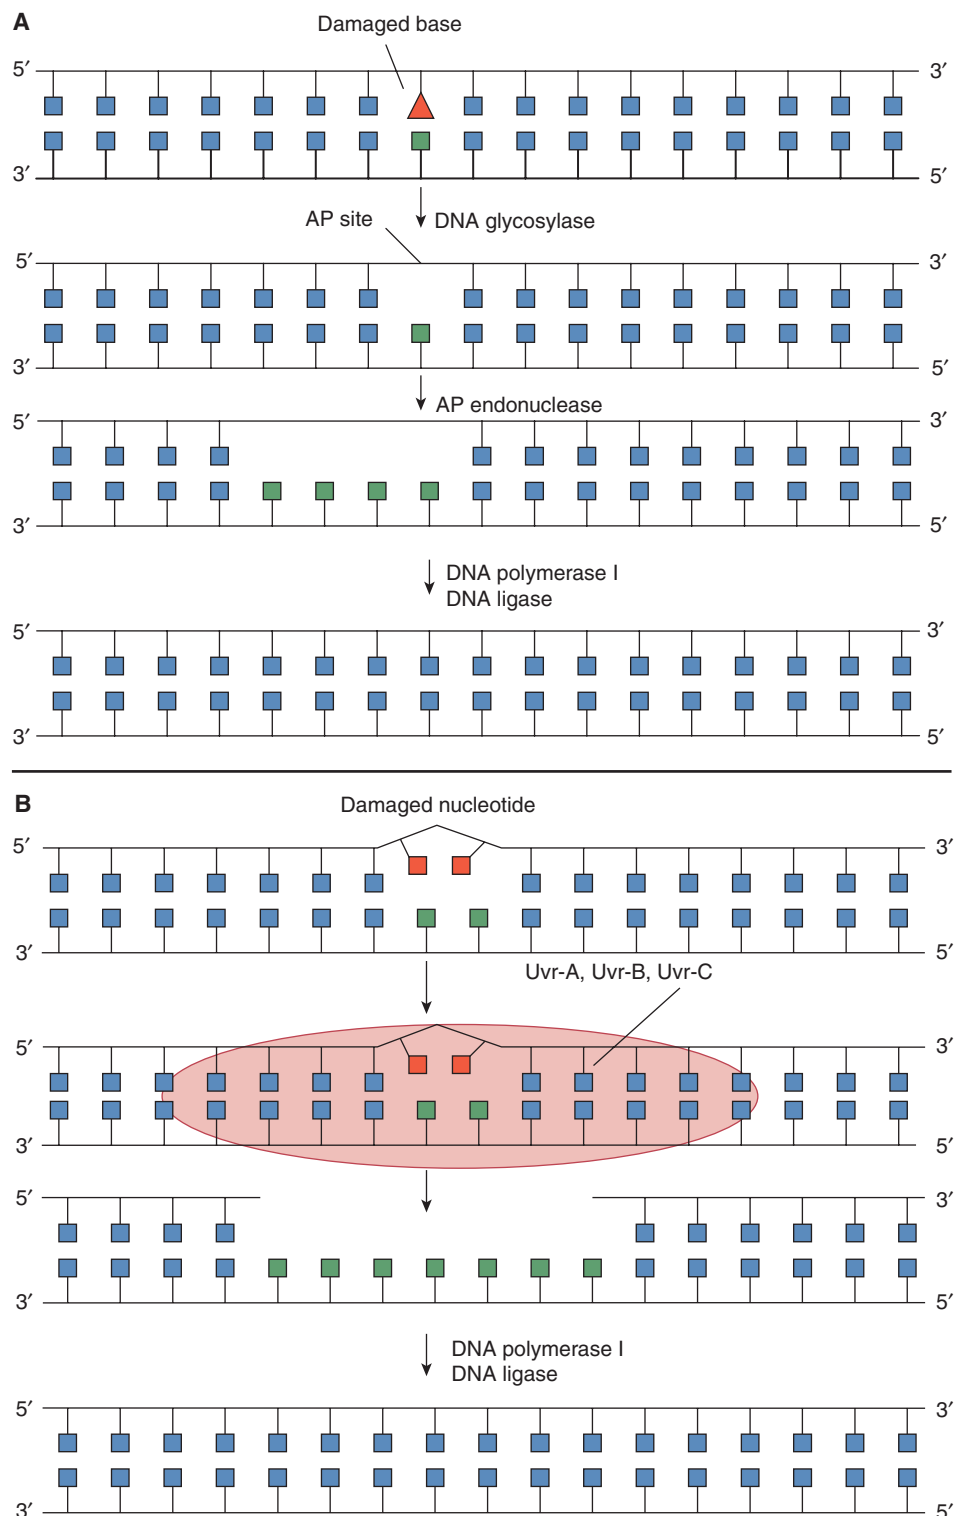

Figure 8-9. (A), DNA repair by base excision. (B), DNA repair by nucleotide excision.

Figure 8-10. (A), Chemical structures of selected carcinogenic polycyclic hydrocarbons. (B), Role of epoxide hydrolase in the inactivation of benzo[*a*]pyrene 4,5-oxide and in the conversion of benzo[*a*]pyrene to its tumorigenic Bay region diolepoxide.

(IARC monographs [Vol. 100 A–F]). Benzo(*a*)pyrene is a representative polycyclic hydrocarbon that has been extensively studied. The metabolism and pathways that lead to tumor formation have been characterized through the work of a number of laboratories (Conney, 1982). The ultimate carcinogen is a diol epoxide of benzo(*a*)pyrene, formed following three separate enzymatic reactions (Sims *et al.*, 1974). Benzo[*a*]pyrene is first oxidized by cytochrome P4501A1 to form benzo[*a*]pyrene 7,8-oxide, further metabolized by epoxide hydrolase, yielding the 7,8-dihydrodiol.

And then further metabolism by cytochrome P4501A1 to yield the ultimate carcinogen, the 7,8-dihydrodiol-9,10-epoxide (Yang *et al.*, 1976; Lowe and Silverman, 1984). The Bay region or K region of the benzo(*a*)pyrene molecule is the site of metabolic targeting and DNA interaction (Fig. 8-10B). The importance of the Bay region (K region) of the benzo(*a*)pyrene molecule was demonstrated from the understanding of the metabolism of the benzo(*a*)pyrene to its ultimate DNA-reactive form. Similar regions (to the Bay region) have been identified in other carcinogenic polycyclic hydrocarbons and

used to access and predict carcinogenic potential of other PAHs. Evidence has emerged that besides the P450 metabolism pathway, PAHs can also be metabolized through a peroxidase pathway and the aldo-keto reductase (AKR) pathway. The latter of which has been attributed to cancer risk in humans exposed to coal burning smoke in China (Lan *et al.*, 2004). Oxidative damage-related genes AKR1C3 and OGG2 also appear to modulate risks for lung cancer due to exposure to PAH-rich coal combustion emissions.

Alkylating Agents Alkylating agents represent an important class of chemical carcinogens. Although some alkylating agents are direct-acting genotoxic agents, many require metabolic activation to produce electrophilic metabolites that can react with DNA. Alkylating agents can be classified into several groups including the direct-acting alkylalkanesulfonates (methyl- and ethyl methanesulfonate) and nitrosamides (*N*-methyl-*N*-nitrosourea, *N*-ethyl-*N*-nitrosourea, *N*-methyl-*N*-nitro-*N*-nitrosoguanidine, and the indirect-acting nitrosamides (dimethyl- and diethylnitrosamines) (Fig. 8-11). The alkylating compounds (or in the case of diethylnitrosamine and dimethylnitrosamine and their metabolites) readily react with DNA at more than 12 sites. The *N*⁷ position of guanine and the *N*³ position of adenine are the most reactive sites for alkylating chemicals to bind to DNA. DNA methylation reactions occur more readily and thus exhibit >20 more adduct formation compared with ethylation reactions. However, ethylation reactions have a greater affinity for oxygen centers, an event that appears to correlate with the mutagenicity and carcinogenicity of these compounds. Nitrosamines were initially used as solvents in chemistry. Their toxic effects were identified when workers using the nitrosamines

Dialkyl nitrosamines

*N*-Nitrosoureas*N*-Alkyl-*N'*-nitro-*N*-nitrosoguanidine

Figure 8-11. Structures of representative methylating and ethylating agents.

solvents developed jaundice and liver damage. Subsequent studies in animal models revealed that dimethylnitrosamine, and eventually diethylnitrosamine were highly hepatotoxic and hepatocarcinogenic.

Other alkylating chemicals including the nitrogen mustards (eg, chlorambucil, cyclophosphamide) have been used in cancer chemotherapy. They produce DNA adducts as well as induce the formation of DNA strand breaks. The alkylation of DNA by nitrogen mustards requires the formation of highly reactive *N*-alkylaziridinium ions (Fig. 8-12). Nitrogen mustards can produce

Cyclophosphamide

Chlorambucil

Figure 8-12. Nitrogen mustards and proposed mechanism for the reactions of nitrogen mustards with DNA.

Figure 8-13. Chemical structures for ethylene and propylene oxide.

a wide spectrum of mutations including base pair substitutions (AT and GC) and deletions. In addition, nitrogen mustards are potent clastogens causing chromosomal aberrations and sister chromatid exchanges (SCEs), predominantly in GC-rich regions.

Ethylene oxide and propylene oxide are other examples of mutagenic and carcinogenic alkylating agents (Fig. 8-13). Ethylene oxide is a direct-acting alkylating carcinogen in rodents and perhaps of human concern (Hogstedt *et al.*, 1986). Ethylene oxide is mutagenic in short-term *in vitro* assays and produces chromosomal aberrations and SCEs in eukaryotic cells (Ehrenberg and Hussain, 1981). Propylene oxide is also a mutagenic rodent carcinogen inducing nasal tumors in rodents following inhalation exposure (NTP, 1985). Alkylation of DNA by ethylene and propylene oxide occurs predominantly at the *N*⁷ position of guanine, yielding 7-(2-hydroxyethyl)guanine and 7-(2-hydroxypropyl)guanine adducts, respectively. These adducts represent the major adducts formed following either *in vitro* or *in vivo* exposure (Walker *et al.*, 1992).

Vinyl chloride is another known rodent and human carcinogen, producing angiosarcomas in the liver and tumors in the lung and hematopoietic system in humans (Doll, 1988). Limited evidence also suggests that vinyl chloride exposure results in brain tumors. Vinyl chloride is mutagenic and is metabolized by cytochrome P450 to form chloroethylene oxide, which rearranges nonenzymatically to produce chloroacetaldehyde, both of which can alkylate DNA. Vinyl chloride and metabolites form several DNA adducts including 7-(2'-oxoethyl)guanine, *N*², 3-etheneoguanine, 3,*N*⁴-ethenocytosine, and 1,*N*⁶-ethenoadenine (Guengerich, 1994).

Aromatic Amines and Amides Aromatic amines and amides encompass a class of chemicals with varied structures (aromatic amines, eg, aniline dyes, 2-naphthylamine, benzidine, 2-acetylaminofluorene) (Fig. 8-14). Because of their use in the dye industry and other industrial processes their carcinogen risk to humans was realized in the late 19th century. Exposure to these chemicals still occurs through cigarette smoke and environmental sources, even though proper industrial hygiene processes have considerably reduced the human exposure to aromatic amines and amides in the workplace. The aromatic amines undergo both phase I and phase II metabolism. Phase I reactions occur mainly by cytochrome P450-mediated reactions, yielding hydroxylated metabolites that are often associated with adduct formation in proteins and DNA, and produce liver and bladder carcinogenicity (Miller *et al.*, 1964). Metabolism of 2-acetylaminofluorene (AAF) results in the formation of *N*-hydroxy-AAF, which is a metabolite responsible for the liver tumorigenicity. Similarly, 1-naphthylamine exhibits carcinogenic activity only in test systems capable of producing the *N*-hydroxy metabolite of naphthylamine. Aromatic amines are capable of forming adducts with several DNA bases. Both heterocyclic amines (HCAs) and PAHs are formed when muscle meat, including beef, pork, fish, and poultry, is cooked using high-temperature

Figure 8-14. Chemical structures of selected carcinogenic aromatic amines.

methods, such as pan frying or grilling directly over an open flame. HCAs are also formed from fried foods, specifically fried meats (Turesky, 2007). Mutagenic activity of cooked meats at high temperature has been reported using the Ames Salmonella mutagenesis assay. In particular, an increase in HCAs (specifically MeIQx(2-amino-3,8-dimethylimidazo[4,5-*b*]quinoxaline), DiMeIQx (2-amino-3,4,8-dimethylimidazo [4,5-*f*]quinoxaline), and IQ (2-amino-3-methylimidazo [4,5-*f*]quinolone)) were found with increasing frying temperatures and cooking duration (Knize *et al.*, 1995). In support of these experimental studies epidemiology linkages between consumption of high-temperature cooked foods and human cancer have been reported (Cross and Sinha, 2004; Rohrmann *et al.*, 2007).

Classes and Mode of Action of Nongenotoxic (Epigenetic) Carcinogens

A number of chemicals that produce tumors in experimental animals following chronic treatment appear to act via mechanisms not involving direct binding, damage, or interaction of the chemical or its metabolites with DNA (Williams and Whysner, 1996). Based on the lack of genotoxicity, yet their ability to induce tumors in rodent models, these chemicals have been labeled nongenotoxic carcinogens. The organ and tissue targets induced by nongenotoxic carcinogens are many times in tissues where a significant incidence of background, spontaneous tumors is seen in the animal model. Prolonged exposure to relatively high levels of chemicals is usually necessary for the production of tumors. In addition, with nongenotoxic carcinogens, tumors are not theoretically expected to occur at exposures below a threshold at which relevant cellular effects are not observed. In contrast to DNA-reactive genotoxic effects, non-DNA-reactive mechanisms may be unique to the rodent species used for testing. Certain chemical carcinogens have been well studied and provide examples for the use of mechanistic information in risk assessment. Further, the biochemical modes of action for non-DNA-reactive carcinogens are diverse. Examples include chemicals that function via sustained cytotoxicity, receptor-mediated (eg, CAR, peroxisome proliferator-activated receptor alpha [PPAR α], aryl hydrocarbon receptor [AhR]) effects, hormonal perturbation, as well as the induction of oxidative stress and modulation of methylation status (Table 8-10). Each of these potential mechanisms is discussed in greater detail in the following sections.

Cytotoxicity Cytotoxicity and consequent regenerative hyperplasia is well-documented mode of action for a variety of non-DNA-reactive chemical carcinogens (Dietrich and Swenberg, 1991). Chloroform-induced liver and kidney tumors and melamine-induced bladder tumors are classic examples of chemical carcinogens that are classified as functioning via a cytolethal mode of action (Andersen *et al.*, 1998; Bull *et al.*, 1986; Pereira, 1994; Larson *et al.*, 1994; Butterworth *et al.*, 1990). Chemicals that function through this mechanism produce sustained cell death, often related to metabolism of the chemical, that is accompanied by persistent regenerative growth, resulting in the potential for the acquisition of “spontaneous” DNA mutations and allowing mutated cells to accumulate and proliferate. This process then gives rise to preneoplastic focal lesions that upon further expansion can lead to tumor formation. Chloroform has been shown to induce mouse liver tumors only at doses of compound that produce liver necrosis, thus demonstrating an association between necrosis with compensatory hyperplasia and the resulting tumorigenicity, and also supports that a threshold for the induction of tumors is likely at doses that do not produce toxicity. It is important to note that the

Table 8-10

Proposed Modes of Action for Selected Nongenotoxic Chemical Carcinogens

MODE OF ACTION	EXAMPLE
<i>Cytotoxicity</i>	Chloroform Melamine

induction of cytotoxicity may be observed with many carcinogens both genotoxic and nongenotoxic when high toxic exposures occur. Thus, the induction of cytotoxicity with compensatory hyperplasia may contribute to the observed tumorigenicity of many carcinogenic agents at high-dose levels.

α 2u-Globulin-Binding Drugs The carcinogens D-limonene, 1,4-dichlorobenzene, and trimethylpentane (Fig. 8-15) induce renal tumors selectively in the male rat, and provide excellent examples of the species, sex, and tissue specificity of non-DNA-reactive carcinogens. The mechanism for the species and sex specificity is related to the ability of these compounds to bind to α 2u-globulin, a protein synthesized by the male rat liver at the onset of puberty, as the mechanism of tumorigenesis. α 2u-Globulin is filtered through the glomerulus, and only partially excreted (~50%) in the urine. The reabsorbed fraction accumulates in lysosomes of the P2 segment of the proximal tubules, where it is hydrolyzed to amino acids (Melnick *et al.*, 1996). Chemicals with the ability to bind to α 2u-globulin decrease the rate of digestion of α 2u-globulin and results in the accumulation in the lysosomes, dysfunction of this organelle and subsequent release of digestive enzymes and cell necrosis. The greater loss of tubule cells leads to increased cell proliferation in the P2 segment, which may be responsible for the tumor development and malignant transformation (Dietrich and Swenberg, 1991).

Figure 8-15. Examples of selective $\alpha 2u$ -globulin-binding chemicals.

Receptor-Mediated

CAR Receptor-Mediated (Phenobarbital-Like Carcinogens)

Phenobarbital is a commonly studied non-DNA-reactive compound that is known to cause tumors by a nongenotoxic mechanism involving liver hyperplasia (Williams and Whysner, 1996). One feature seen following phenobarbital exposure is the induction of P450 enzymes, particularly Cyp2b (Nims and Lubet, 1996). Because a number of diverse chemicals are known to induce various members of the P450 system (eg, dieldrin, ethanol, 2,3,7,8-Tetrachlorodibenzo-*p*-dioxin [TCDD]), the specificity of this effect to the carcinogenesis has been questioned. Recent evidence has shown that the induction of Cyp2b is mediated by activation of the constitutive androstane receptor (CAR), a member of the nuclear receptor family (Ueda *et al.*, 2002; Kodama *et al.*, 2004; Honkakoski *et al.*, 1998). CAR-null mice show no induction of Cyp2b following phenobarbital exposure (Wei *et al.*, 2000). Other phenobarbital responses that are critical for tumor formation include increased cell proliferation, inhibition of apoptosis, inhibition of gap junctional communication, hypertrophy, and development of preneoplastic focal lesions in the liver (Whysner *et al.*, 1996), effects that have all been shown to be CAR-dependent (Wei *et al.*, 2000; Kodama *et al.*, 2004) (Fig. 8-16).

Peroxisome Proliferator-Activated Receptor α . A wide array of chemicals are capable of increasing the number and volume of peroxisomes in the cytoplasm of cells. These agents, termed peroxisome proliferators, include chemicals such as herbicides, chlorinated solvents (eg, trichloroethylene and perchloroethylene) plasticizers (eg, diethylhexylphthalate and other phthalates), lipid-lowering fibrate drugs (eg, ciprofibrate, clofibrate), and natural products. In addition, many of the chemicals within this group produce liver enlargement and hepatocellular carcinoma in rats and mice through non-DNA-reactive mechanisms (Lake, 1995; Reddy and Rao, 1997). Two additional tumor types are also associated with exposure to peroxisome proliferating compounds: Leydig cell tumors and pancreatic acinar cell tumors in rats. Studies conducted either *in vivo* or *in vitro* in primary hepatocyte cultures have shown important interspecies differences in the hepatic peroxisome proliferation responses to chemicals within the class of compounds. The rat and the mouse were clearly revealed as responsive species, whereas primates and the guinea pig proved to be nonresponders. The Syrian hamster exhibits an intermediate response (Lake, 1995; Bentley *et al.*, 1993). Due to the wide structural diversity of this chemical class, the mechanism(s) involved in peroxisome proliferation and tumorigenesis went unrecognized for years. The currently accepted mode of action for this class of chemicals involves agonist binding to a nuclear hormone receptor, the PPAR α . Largely through the use of PPAR α knockout mice, it has been demonstrated that the activation of PPAR α by agonists is needed for these chemicals to induce peroxisome proliferation and tumorigenesis in rodents (Issemann and Green, 1990; Lee *et al.*, 1995; Peters *et al.*, 1998, reviewed in Klaunig *et al.*, 2003). PPAR α is highly expressed in cells that have active fatty acid oxidation capacity (eg, hepatocytes, cardiomyocytes, enterocytes). It is well documented that PPAR α plays a central role in lipid metabolism and acts as a transcription factor to modulate gene expression following ligand activation. This latter effect arises through the heterodimerization of PPAR α and RXR α , which results in binding to

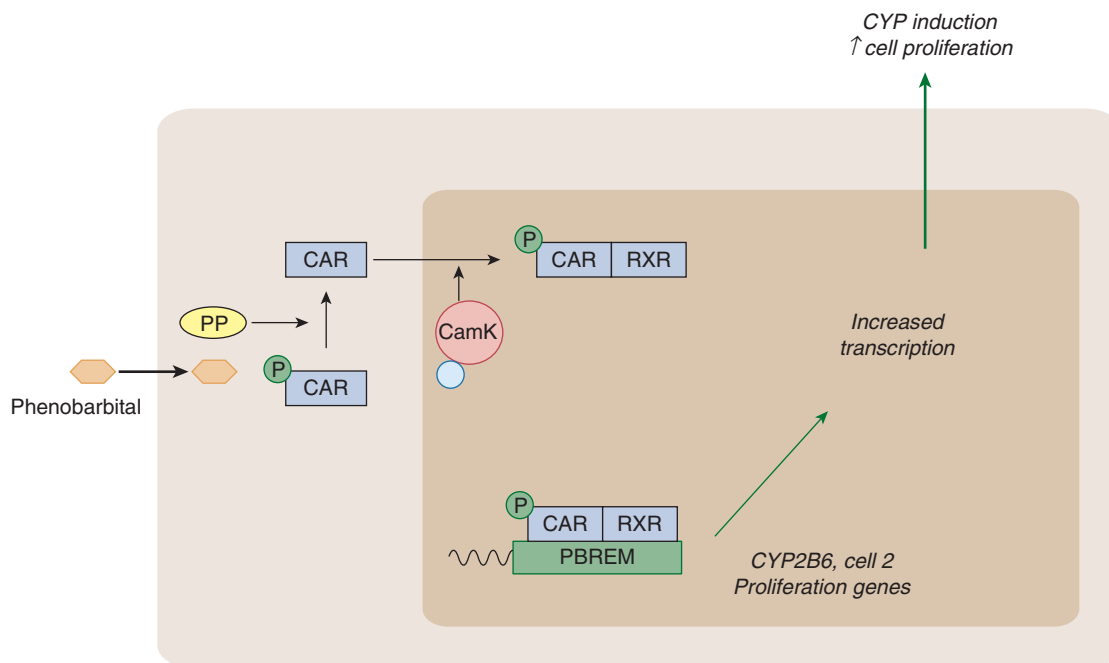

Figure 8-16. Proposed mechanism for the involvement of the constitutive androstane receptor (CAR) in phenobarbital-induced gene expression changes. PP, protein phosphatase; CamK, CaM Kinase; RXR, retinoic acid receptor; PBREM, phenobarbital response element. Following dephosphorylation of CAR by protein phosphatase, CAR crosses the cell membrane and becomes phosphorylated by CaM kinase. CAR then forms a dimer with RXR and binds to PBREMs, resulting in increased gene expression.

Figure 8-17. Mechanism for altered gene expression by peroxisome proliferator activated receptor α (PPAR α) agonist binding. Following agonist binding to PPAR α , the receptor dimerizes with the retinoic acid receptor (RXR). This complex then binds to PPREs, resulting in enhanced gene transcription.

response elements (PPREs) and subsequent modulation of target gene transcription (Fig. 8-17). Following this event is the induction of cell proliferation and suppression of apoptosis (Marsman *et al.*, 1992; Burkhardt *et al.*, 2001; James and Roberts, 1996). Both of these events would then be expected to affect tumor development as these effects would enhance the rate of fixation of DNA damage in the genome, leading to changes in gene expression, such as the silencing of tumor-suppressor genes or increased expression of oncogenes, or suppress apoptosis that may normally remove DNA-damaged, potentially tumorigenic, cells. Because humans are exposed to a number of these chemicals, the relevance of this mode of action to humans has been evaluated (Klaunig *et al.*, 2003). Although the same events would be expected to occur in exposed humans, several species differences have been noted including a lack of induction of cell proliferation in nonhuman primates (Pugh *et al.*, 2000), and the finding that PPAR α in human liver is at least 10-fold lower compared with the rat or mouse (Palmer *et al.*, 1998; Tugwood *et al.*, 1998). Based on these kinetic and dynamic differences between species, it has been concluded that tumors are not likely to occur in humans by PPAR α agonists (Klaunig *et al.*, 2003).

Aryl Hydrocarbon Receptor Activators of the AhR receptor including TCDD and selected polychlorinated- and brominated-biphenyl (PCBs and PBBs) compounds (Fig. 8-18) have been linked to tumor promotion in rodent livers (IARC, 1997a,b; 2011; Pitot *et al.*, 1982). The tumor response has been determined to be AhR-dependent (Knutson and Poland, 1982) (Fig. 8-19). Upon ligand binding to the AhR, the ligand bound AhR translocates to the nucleus, dimerizes with the Ah receptor nuclear translocator (ARNT) and binds to aryl hydrocarbon response elements (AREs also known as doxin response elements [DRE] and xenobiotic response elements [XRE]) (for review see Nebert *et al.*, 2000). AhR-ARNT-dependent genes include cytochrome P450 family members, NAD(P)H:quinone oxidoreductase, a cytosolic aldehyde dehydrogenase 3, a UDP-glucuronosyltransferase, and a glutathione transferase (Nebert *et al.*, 2000), genes that are involved in metabolic activation as well as detoxification of chemical agents. It has been hypothesized that there are additional AhR-ARNT-dependent genes (Nebert *et al.*, 2000). AhR knockout mice have a diminished response to tumor induction by AhR ligands (Nakatsuru *et al.*, 2004), and conversely, constitutively overexpressed AhR resulted in an increased incidence of liver tumors (Moennikes *et al.*, 2004).

Figure 8-18. Selective examples of aryl hydrocarbon receptor-binding chemicals. Prototypical structure for PCBs or PBBs. PCBs and PBBs exhibit varying degrees of chlorination or bromination at positions 2-6 and 2'-6' of the biphenyl molecule.

As seen with other hepatic tumor-promoting chemicals, TCDD also inhibits apoptosis in hepatic foci (Stinchcombe *et al.*, 1995).

Hormonal Mode of Action Hormonally active chemicals include steroids and peptide hormones that produce tissue-specific changes through interaction with a receptor. A number of non-DNA-reactive chemicals induce neoplasia through receptor-mediated mechanisms, and/or perturbation of hormonal balance. Trophic hormones are known to induce cell proliferation at their target organs. This action may lead to the development of tumors when the mechanisms of hormonal control are disrupted and some or other hormone shows persistently increased levels. Several well-studied examples include the induction of ovarian neoplasms via decreased estradiol and increased luteinizing hormone (LH) levels (Capen *et al.*, 1995), and the induction of thyroid tumors in rats by phenobarbital-type P450 inducers (which modulate T3 and T4) (McClain, 1994; Whysner *et al.*, 1996).

Figure 8-19. Proposed mechanism of aryl hydrocarbon receptor (AhR) mediated gene expression. ARNT, AhR nuclear transporter; XRE, xenobiotic response element. Non-ligand bound AhR is maintained in the cytoplasm via association with chaperone proteins (eg, AIP, Hsp90). Following ligand binding, chaperone proteins dissociate and AhR translocates to the nucleus where it binds with ARNT. The heterodimer binds to XREs resulting in an increase in gene transcription.

Figure 8-20. Chemical examples of estrogenic agonists and antagonists.

Estrogenic agents can induce tumors in estrogen-dependent tissue. Selective estrogenic agents (agonists and antagonists) are shown in Fig. 8-20. Oral administration of 17β-estradiol to female mice increases the incidence of mammary tumors (Welsch *et al.*, 1977; Highman *et al.*, 1978) whereas subcutaneous administration of estradiol to young female mice produced tumors of the cervix and vagina (Pan and Gardner, 1948). Evidence that estrogenic chemicals are carcinogenic to humans comes from epidemiological data on breast and ovarian cancer, which indicates that individuals with higher circulating estrogen levels and those with exposure to the potent estrogenic chemical diethylstilbesterol (DES) are at increased risk for cancer development. DES was first shown to induce mammary tumors in male mice following subcutaneous administration of the hormone. DES has been causally associated to the higher incidence of adenocarcinomas of the vagina and cervix in daughters of women treated with the hormone during pregnancy (Herbst and Scully, 1970; Herbst *et al.*, 1972; Noller *et al.*, 1972). The mechanism of action for DES is believed to function through its ability to induce aneuploidy (Tsutsui *et al.*, 1997; Li *et al.*, 1997). The effects of steroidal chemicals on the cell cycle (Sutherland *et al.*, 1995) and on microtubule assembly (Metzler *et al.*, 1996) may be important in the aneuploidy inducing effects of some hormonal agents (Li *et al.*, 1996).

Chronic exogenous administration of hormonally active chemicals including synthetic estrogens and anabolic steroids can increase hepatic adenoma incidence in rats (Li *et al.*, 1992) and in humans (IARC, 1997a,b). Women of childbearing age are sensitive to hepatic adenoma formation, which can be exacerbated by oral contraceptive use. These adenomas will regress upon hormone cessation (Edmondson *et al.*, 1977) and can progress with continued administration (Christopherson *et al.*, 1978). Chronic administration (>8 years) is required to detect this increased liver tumor risk from oral contraceptives (Tavani *et al.*, 1993).

Many substances in plants (phytoestrogens) have been described. These include compounds such as genestein, daidzein,

glycetein, equol, and their metabolites found in soy products and various lignan derivatives (Adlercreutz and Mazur, 1997). In addition, a number of environmental nonsteroidal synthetic compounds demonstrate apparent estrogenic activity (eg, nonyl-phenol, bisphenol-A, chlorinated hydrocarbons; Soto *et al.*, 1997). The potential for these chemicals to induce cancer in humans is an area of current investigation.

Species and tissue specificity in response to receptor- and hormone-mediated carcinogenesis is often observed. As an example, tamoxifen is antiestrogenic in the chick oviduct, estrogenic in the mouse uterus with acute administration, but antiestrogenic with chronic administration in the same tissue, whereas it is estrogenic in the rat uterus. Although this may be in part due to tissue and species differences in coactivator and corepressor levels and availability, many other pharmacokinetic and pharmacodynamic properties are likely to participate (Carthew *et al.*, 1995). To further exemplify the complexity of the role of estrogen in cancer development, estrogens have also been shown to act as a protective agent in prostate cancer.

Induction of ovarian tumors by dietary administration of nitrofurantoin in mice is an example of a tumorigenic effect secondary to drug-induced hormonal disturbance. Treatment resulted in ovarian atrophy with absence of graafian follicles and sterility. The reduction of follicles induced a reduction of sex steroid hormone by the ovary, resulting in increased production of gonadotrophins, notably LH, presumably due to the decreased negative feedback on the hypothalamus-pituitary axis by estrogens. Persistent stimulation by LH of the ovary cells resulted in development of tumors (Capen *et al.*, 1995). A similar effect is known to occur with dopamine agonists. The induction of hypoprolactinemia changes the number of LH receptors and leads to enhanced sensitivity to LH and a higher stimulation by LH similarly to nitrofurantoin.

A reduction of thyroid hormone concentrations (T4 and/or T3) and increased thyroid-stimulating hormone (TSH) have been

Figure 8-21. Mechanism for phenobarbital-induced thyroid tumors. Through alteration of gene expression, phenobarbital enhances metabolism of thyroid hormone (T3) resulting in enhanced TSH production. Increased TSH then leads to increased cell proliferation in the thyroid.

shown to induce neoplasia in the rodent thyroid. TSH increases proliferative activity in the thyroid. After chronic treatment chemical-induced TSH increases leading to follicular cell hypertrophy, hyperplasia, and eventually neoplasia. Inducers of metabolic enzymes in the liver, a classic and well-studied example being phenobarbital (Hood *et al.*, 1999), result in increased thyroid hormone metabolism and as such lead to increase in TSH levels (Fig. 8-21). It is this latter event that is associated with the development of thyroid tumors in rodents. Recent evidence suggests that the enhancement of metabolism and excretion of thyroid hormones by xenobiotics (via induction of phase II enzymes) is a consequence of CAR (and presumably PXR) activation. Qualitatively, thyroid gland function in rodents is much more susceptible to disturbances of the thyroid hormone levels than it is in humans. In contrast to humans, rodents lack the thyroid-binding globulin, which is the predominant plasma protein (at least in humans) responsible for

thyroxin binding and transport (McClain, 1995). A relatively higher level of functional activity is present in rat thyroid compared to humans.

DNA Methylation and Carcinogenesis Post-DNA synthetic methylation of the five position on cytosine (5-methylcytosine; 5mC) is a naturally occurring modification to DNA in higher eukaryotes that influences gene expression (Holliday, 1990) (Fig. 8-22). Under normal conditions, DNA is methylated symmetrically on both strands. Immediately following DNA replication, the newly synthesized double-stranded DNA contains hemimethylated sites that signal for DNA maintenance methylases to transfer methyl groups from S-adenosylmethionine to cytosine residues on the new DNA strand (Hergersberg, 1991). The degree of methylation within a gene inversely correlates with the expression of that gene; hypermethylation of genes is associated with gene silencing whereas hypomethylation results in an enhanced expression of genes. Several chemical carcinogens are known to modify DNA methylation, methyltransferase activity, and chromosomal structure. During carcinogenesis, both hypomethylation and hypermethylation of the genome have been observed (Counts and Goodman, 1995; Baylin, 1997). Increased methylation of CpG islands have been observed in bladder cancer and tumor-suppressor genes such as the retinoblastoma gene, *p16^{ink4a}*, and *p14^{ARF}* have been reported to be hypermethylated in tumors (Salem *et al.*, 2000; Stirzaker *et al.*, 1997; Myöhänen *et al.*, 1998; Esteller *et al.*, 2001; Belinsky *et al.*, 1998). Hypomethylation has been associated with increased mutation rates. Most metastatic neoplasms in humans have significantly lower 5mC than normal tissue (Gama-Sosa *et al.*, 1983); furthermore, many oncogenes are hypomethylated and their expression amplified.

Choline and methionine, which can be derived from dietary sources, provide a source of methyl groups used in methylation reactions. Rats exposed to choline and/or methionine-deficient diets resulted in hepatocellular proliferation and neoplasia (Abanobi

Figure 8-22. Substrates and products involved in DNA methylation. Methylation of DNA occurs through an enzymatic reaction catalyzed by DNA methyltransferases (DNMTs). DNA is methylated at the five-position of cytosine and requires the cofactor S-adenosyl methionine.

Table 8-11

Evidence for Choline Depletion in Hepatocarcinogenesis

CHOLINE	METHIONINE	FOLATE	HEPATOCELLULAR CARCINOMA (%)	DURATION (MONTHS)	REFERENCES
–	+	+	100	12	Nakae <i>et al.</i> (1992)

et al., 1982; Wainfan and Poirier, 1992) (Table 8-11). In rodents fed choline or methyl donor groups deficient diets, the hepatic neoplasia is thought to arise from hypomethylation of *c-myc*, *c-fos*, and *c-H-ras* proto-oncogenes, due to the decreased availability of S-adenosylmethionine (Wainfan and Poirier, 1992; Newberne *et al.*, 1982). Chemicals such as diethanolamine result in hepatic neoplasia, in part, via a mechanism involving choline depletion, altered methylation and modulation of gene expression (Bachman *et al.*, 2006; Kamendulis and Klaunig, 2005). Reactive oxygen species have also been shown to modify DNA methylation resulting in changes in DNA methylation profiles through interfering with the ability of methyltransferases to interact with DNA, leading to hypomethylation of CpG sites (Weitzman *et al.*, 1994; Turk *et al.*, 1995). Also, the presence of 8-OHdG in DNA can lead to hypomethylation of DNA because this adduct, if present in CpCpGpGp sequences, will inhibit the methylation of adjacent C residues. Thus, oxidative DNA damage may be an important contributor to the carcinogenesis process brought about by the loss of DNA methylation, allowing the expression of normally quiescent genes. Also, the abnormal methylation pattern observed in cells transformed by chemical oxidants may contribute to an overall aberrant gene expression and promote the tumor process.

Oxidative Stress and Chemical Carcinogenesis Experimental evidence has shown that increases in reactive oxygen in the cell, through either physiological modification or chemical carcinogen exposure, contribute to the carcinogenesis processes (Guyton and Kensler, 1993; Trush and Kensler, 1991; Vuillaume, 1987; Witz, 1991). Reactive oxygen species encompass a series of reactive compounds including the superoxide anion ($\text{O}_2^{\cdot-}$), hydroperoxyl radical (HO_2^{\cdot}), hydrogen peroxide (H_2O_2), and the hydroxyl radical (OH^{\cdot}), all derived through the reduction of molecular oxygen (Table 8-12). Oxygen radicals can be produced by both endogenous and exogenous sources and are typically counterbalanced by antioxidants (Table 8-13). Antioxidant defenses are both enzymatic

Table 8-12

Pathways for Intercellular Oxidant Generation

Generation of Reactive Oxygen Species via Reduction of Molecular Oxygen

A series of oxygen radicals are produced by the reduction of molecular oxygen. Of the radicals produced, the hydroxyl radical, hydroperoxyl radical, and the superoxide anion are sufficiently reactive and may interact with biomolecules.

(eg, superoxide dismutase, glutathione peroxidase, and catalase) and nonenzymatic (eg, vitamin E, vitamin C, β -carotene, and glutathione) (Betteridge, 2000; Abuja, 2001); importantly, many of these antioxidants are provided through dietary intake (Clarkson and Thompson, 2000).

Endogenous sources of reactive oxygen species include oxidative phosphorylation, P450 metabolism, peroxisomes, and inflammatory cell activation (Table 8-13). Within the mitochondria, a small percentage of oxygen is converted into the superoxide anion via 1-electron reduction of molecular oxygen. Superoxide can be dismutated by superoxide dismutase to yield hydrogen peroxide (Barber and Harris, 1994). In the presence of partially reduced metal ions hydrogen peroxide is converted into the highly reactive hydroxyl radical through Fenton and Haber–Weiss reactions (Betteridge, 2000). Neutrophils, eosinophils, and macrophages represent another intracellular source of reactive oxygen species. Activated macrophages, through a “respiratory burst,” elicit a rapid increase in oxygen uptake that gives rise to a variety of reactive

Oxidants > Antioxidants → Oxidative Damage (DNA, RNA, Lipid, Protein)

Oxidants can be produced via both endogenous and exogenous sources. Antioxidants function to maintain the cellular redox balancing. However, excess production of oxidants and/or inadequate supplies of antioxidants result in damage to cellular biomolecules and may impact on neoplastic development.

oxygen species including superoxide anion, hydrogen peroxide, and nitric oxide. The release of cytokines and reactive oxygen intermediates from activated Kupffer cells (the resident macrophage of the liver) has been implicated in hepatotoxicological and hepatocarcinogenic events (Rose *et al.*, 1999; Rusyn *et al.*, 1999); in particular, recent studies show that the Kupffer cell may function at the promotion stage of carcinogenesis. Reactive oxygen species can also be produced by cytochrome P450-mediated mechanisms including (1) redox cycling in the presence of molecular oxygen, (2) peroxidase-catalyzed single electron drug oxidations, and (3) “futile cycling” of cytochromes P450 (Parke, 1994; Parke and Sapota, 1996). Ethanol, phenobarbital, and a number of chlorinated and nonchlorinated compounds such as dieldrin, TCDD, and lindane are among the xenobiotics shown to increase reactive oxygen species through P450-mediated mechanisms (Eksrom and Ingleman-Sundberg, 1989; Rice *et al.*, 1994; Klaunig *et al.*, 1997). Chemicals classified as PPAR α agonists (eg, clofibrate, phthalate esters) represent chemicals that induce cytochrome P450A and increase the formation of peroxisomes. As such, an increase in H₂O₂ production often accompanies exposure to chemicals that stimulate the number and activity of peroxisomes (Rao and Reddy, 1991; Wade *et al.*, 1992). Through these or other currently unknown mechanisms, a number of chemicals that induce cancer (eg, chlorinated compounds, radiation, metal ions, barbiturates, and some PPAR α agonists), induce reactive oxygen species formation and/or oxidative stress (Rice-Evans and Burdon, 1993; Klaunig *et al.*, 1997, 2011).

Oxidative DNA Damage and Carcinogenesis Reactive oxygen species left unbalanced by antioxidants can result in damage to cellular macromolecules. In DNA, reactive oxygen species can produce single- or double-stranded DNA breaks, purine, pyrimidine, or deoxyribose modifications, and DNA cross-links (von Sonntag, 1987; Dizdaroglu, 1992; Demple and Harrison, 1994). Persistent DNA damage can result in either arrest or induction of transcription, induction of signal transduction pathways, replication errors, and genomic instability, events that are potentially involved in carcinogenesis. Oxidation of guanine at the C8 position, results in the formation of 8-hydroxydeoxyguanosine (8-OHdG; see Fig. 8-7). This oxidative DNA adduct is mutagenic in bacterial and mammalian cells, produces dose-related increases in cellular transformation, and causes G \rightarrow T transversions that are commonly observed in mutated oncogenes and tumor-suppressor genes (Zhang *et al.*, 2000; Shibutani *et al.*, 1991; Moriya, 1993; Hussain and Haris, 1998). During DNA replication, 8-OHdG in the nucleotide pool can incorporate into the DNA template strand opposite dC or dA resulting in A:T to C:G transversions (Demple and Harrison, 1994; Cheng *et al.*, 1992). Oxidative damage to mitochondrial DNA and mutations in mitochondrial DNA have been identified in a number of cancers (Schumacher *et al.*, 1973; Cavalli and Liang, 1998; Tamura *et al.*, 1999; Horton *et al.*, 1996). Compared to nuclear DNA, the mitochondrial genome is relatively susceptible to oxidative base damage due to (1) close proximity to the electron transport system, a major source of reactive oxygen species (Barber and Harris, 1994); (2) mitochondrial DNA is not protected by histones; and (3) DNA repair capacity is limited in the mitochondria (Sawyer and Van Houten, 1999; Bohr and Dianov, 1999). Although many pathways exist that enable the formation of oxidative DNA damage, mammalian cells also possess specific repair pathways for the remediation of oxidative DNA damage (Tchou and Grollman, 1993; Fortini *et al.*, 1999).

Aside from oxidized nucleic acids, oxygen radicals can damage cellular biomembranes resulting in lipid peroxidation. Peroxidation of biomembranes generates a variety of products including reactive electrophiles such as epoxides and aldehydes, including

malondialdehyde (MDA) (Janero, 1990). MDA is a highly reactive aldehyde and exhibits reactivity toward nucleophiles, and can form MDA–MDA dimers. Both MDA and the MDA–MDA dimers are mutagenic in bacterial assays and the mouse lymphoma assay (Riggins and Marnett, 2001).

Oxidative Stress and Cell Growth Regulation Reactive oxygen species production and oxidative stress can affect both cell proliferation and apoptosis (Burdon, 1995; Slater *et al.*, 1995; Cerutti, 1985). H₂O₂ and superoxide anion can induce cell proliferation in several mammalian cell types (D’Souza *et al.*, 1993). Conversely, high concentrations of reactive oxygen species can initiate apoptosis (Dypbukt *et al.*, 1994). It has clearly been demonstrated that low levels of reactive oxygen species influence signal transduction pathways and alter gene expression (Fiorani *et al.*, 1995). Many xenobiotics, by increasing cellular levels of oxidants, alter gene expression through activation of signaling pathways including cAMP-mediated cascades, calcium-calmodulin pathways, and transcription factors such as AP-1 and NF- κ B as well as signaling through mitogen-activated protein (MAP) kinases (extracellular signal-regulated kinases [ERK], c-Jun N-terminal kinases [JNK], and the p38 kinases) (Muller *et al.*, 1997; Kerr, 1992; Timblin *et al.*, 1997). Activation of these signaling cascades by reactive oxygen species induced by chemical carcinogens ultimately leads to altered gene expression for a number of genes including those affecting proliferation, differentiation, and apoptosis (Chang and Karin, 2001; Martindale and Holbrook, 2002; Brown *et al.*, 1998; Amstad *et al.*, 1992; Hollander and Fornace, 1989; Zawaski, 1993; Pinkus, 1993) (Fig. 8-23). Activation of NF κ B, a ubiquitously expressed

Figure 8-23. Role of reactive oxygen species (ROS) on altered gene expression. Many chemical carcinogens increase ROS and activate signaling cascades, such as the mitogen activated (MAP) kinase family. These serine/threonine kinases activate transcription factors, leading to DNA binding and gene expression changes.

Figure 8-24. Interaction between reactive oxygen species (ROS) and NFκB-induced gene expression. A number of chemicals that increase ROS have been shown to activate NFκB. It is proposed that ROS enhance the dissociation of IκB from the NFκB/IκB complex leading to active NFκB. NFκB can then translocate into the nucleus where it binds DNA and increases gene transcription.

transcription factor, is regulated, in part, by reactive oxygen species and the cellular redox status. NFκB activation has been observed following a variety of extracellular stimuli including exposure to chemical carcinogens and physical agents that induce oxidative stress (Rusyn *et al.*, 2003; Glauert *et al.*, 2002; Beauerle *et al.*, 1988; Pahl, 1999; Li and Karin, 1998; Molina *et al.*, 2001; Schulze-Oshoff *et al.*, 1998; Nebreda and Porrai, 2000) (Fig. 8-24).

Gap Junctional Intercellular Communication and Carcinogenesis

Cells within an organism communicate in a variety of ways including through gap junctions, which are aggregates of connexin proteins that form a conduit between two adjacent cells (Lowenstein *et al.*, 1981) (Fig. 8-25). Gap junctional intercellular communication appears to play an important role in the regulation of cell growth and cell death, in part, through the ability to exchange small molecules (<1 kDa) between cells through gap junctions. Loss of gap junctions or decreased cell-to-cell communication is seen during liver regeneration following partial hepatectomy, a situation in which gap junction expression remains decreased until liver mass and lobular conformation are restored. Aberrant growth control is an essential feature of cancer cells, and because the absence or reduction in cell-to-cell communication has been observed between cancer cells, between cancer and normal cells, and in transformed cells, it has been speculated that altered gap junctional cell communication is involved in carcinogenesis (Trosko and Ruch, 1998). If cell communication is blocked between tumor and normal cells, the exchange of growth inhibitory signals from normal cells would be prevented from acting on initiated cells, thus allowing the potential for unregulated

growth and clonal expansion of initiated cell populations. This would therefore allow for the acquisition of additional genetic changes that may lead to neoplastic transformation (Klaunig and Ruch, 1990).

Intercellular communication is also decreased by growth factor administration and following exposure to a variety of tumor-promoting compounds (eg. phenobarbital, phthalates, dieldrin, phorbol esters). Tumor-promoting chemicals inhibit gap junctional intercellular communication in a number of cell types following

Figure 8-25. Diagram of a gap junction traversing between two adjacent cells. Connexons made up of six connexin proteins form the conduit between the two cells. (Reproduced with permission from Feldman RS, Quenzer LF. *Fundamentals of Neuropsychopharmacology*. Strauer Associates, Inc.; 1984.)

exposure both in vivo and in vitro (Klaunig and Ruch, 1990). The ability of a tumor-promoting compound to block cell-to-cell communication in cultured cells correlates with its ability to induce rodent tumors (Klaunig and Ruch, 1987). In addition, the inhibition of gap junctional intercellular communication by tumor promoters appears to be tissue- and species-specific; they produced inhibition in target organs and sensitive species, whereas they do not inhibit cell-to-cell communication in nontarget tissues for carcinogenicity (Klaunig and Ruch, 1987). The mechanisms by which tumor promoters inhibit intercellular communication are not clear but may be due to decreased synthesis and/or enhanced degradation of gap junction proteins in the cell, reducing the number of channels in cell membranes, or other changes that modulate gap junction function and/or protein expression (Klaunig and Ruch, 1990; Sugie *et al.*, 1987).

Inorganic Carcinogens

Metals Several metals exhibit carcinogenicity in experimental animals and/or exposed humans. Table 8-14 provides a listing of some common metals and their corresponding carcinogenicity in animals and humans. A recent IARC review has examined in detail inorganic compounds deemed human carcinogens (IARC, 2010). Additional details on selected compounds are provided below.

Arsenic Arsenic compounds are poorly mutagenic in both bacterial and mammalian cell assays (Lofroth and Ames, 1978). Metallic arsenic, arsenic trioxide, sodium arsenite, sodium arsenate, potassium arsenite, lead arsenate, calcium arsenate, and pesticide mixtures containing arsenic have been tested for carcinogenicity in experimental animals (IARC, 1980, 1987). In the majority of

studies in experimental animals, including oral-exposure studies in mice, rats, and dogs, dermal-exposure studies in mice, inhalation-exposure studies in mice, injection studies in mice and rats, and intramedullary-injection studies in rats and rabbits, no tumors were observed or the results were inconclusive, and thus it has previously been concluded that limited evidence exists for the carcinogenicity of inorganic arsenic compounds in experimental animals (IARC, 1987).

In contrast, inorganic arsenic compounds are known human carcinogens based on sufficient evidence of carcinogenicity in humans. Epidemiological studies of humans exposed to arsenic compounds demonstrated that exposure to inorganic arsenic compounds increases the risk of cancer in the skin, lung, digestive tract, liver, bladder, kidney, and lymphatic and hematopoietic systems (IARC, 1973, 1980). Several of the epidemiological studies have reported dose-response relationships between arsenic in drinking water and several types of cancer, including bladder, kidney, lung, and skin cancer (Cantor, 1997; Ferreccio *et al.*, 2000). The mechanisms for cancer formation are unclear but are believed to possibly involve the induction of oxidative stress, altered cell signaling, modulation of apoptosis, and/or altered cell cycle (Hughes and Kitchin, 2006; Harris and Shi, 2003; Quian *et al.*, 2003). The latency period in humans of arsenic-related carcinogenesis is considered to be 30 to 50 years. The first signs of chronic exposure, frequently seen in water supplies contaminated with arsenic, are skin pigmentation, depigmentation, hyperkeratosis of palms and soles, and skin lesions. A unique peripheral vascular disease associated with chronic arsenic exposure is black foot disease, starting with numbness and ulceration of extremities and ending in gangrene and spontaneous amputations (Chen *et al.*, 1988).

418 Beryllium Beryllium and its salts are not mutagenic and do not appear to induce cellular transformation (IARC, 1993). Mechanistically, beryllium salts bind to nucleoproteins and inhibit enzymes involved in DNA synthesis, resulting in infidelity of DNA synthesis and also induce gene mutations in cultured cells (Leonard and Lauwerys, 1987). Studies in animal models have consistently reported increases in lung tumors in rodents and non-human primates exposed to beryllium or beryllium compounds (IARC, 1993; Finch *et al.*, 1996; NTP, 1998). Beryllium metal and several beryllium compounds (eg, beryllium-aluminum alloy, beryl ore, beryllium chloride, beryllium hydroxide, beryllium sulfate tetrahydrate, and beryllium oxide) induced lung tumors in rats. Beryllium oxide and beryllium sulfate produced lung cancer (anaplastic carcinoma) in monkeys after intrabronchial implantation or inhalation. In rabbits, osteosarcomas were reported after exposure to beryllium metal, beryllium carbonate, beryllium oxide, beryllium phosphate, beryllium silicate, or zinc beryllium silicate (IARC, 1993).

Beryllium and beryllium compounds have been classified as human carcinogens based on animal studies and evidence of carcinogenicity in humans. Epidemiological studies indicate an increased risk of lung cancer in occupational groups exposed to beryllium or beryllium compounds (Steenland and Ward, 1991; Ward *et al.*, 1992). Furthermore, an association with lung cancer has consistently been observed in occupational populations exposed to beryllium or beryllium compounds. Acute beryllium pneumonitis, a marker for exposure to beryllium, has been shown to be associated with higher lung cancer rates (Steenland and Ward, 1991).

Cadmium Animal studies have shown that cadmium and cadmium compounds induce tumor formation at various sites in multiple species of experimental animals, following multiple exposure routes, including the induction of prostate tumors in rats, testicular tumors in rats and mice, lymphoma in mice, adrenal gland tumors in hamsters and mice, and lung and liver tumors in mice (IARC, 1993; Waalkes *et al.*, 1994; 1999). It has been suggested that ionic cadmium, or compounds that release ionic cadmium, are the cause of genetic damage, and thus the carcinogenic species. Increased frequencies of chromosomal aberrations (changes in chromosome structure or number) have been observed in lymphocytes of workers occupationally exposed to cadmium. Many studies of cultured mammalian cells have shown that cadmium compounds cause genetic damage, including gene mutations, DNA strand breaks, chromosomal damage, cell transformation, and disrupted DNA repair (IARC, 1993).

Cadmium and cadmium compounds have been classified as known human carcinogens based on evidence of carcinogenicity in humans, including epidemiological and mechanistic information that indicate a causal relationship between exposure to cadmium and cadmium compounds and human cancer (9th RoC). Epidemiological studies of cadmium workers found that exposure to various cadmium compounds increased the risk of death from lung cancer (IARC, 1993). Follow-up analysis of some of these cohorts has confirmed that cadmium exposure is associated with elevated lung cancer risk under some industrial circumstances (Sorahan *et al.*, 1995; Sorahan and Lancashire, 1997). Some epidemiological evidence has also suggested an association between cadmium exposure and prostate (Shigematsu *et al.*, 1982; van der Gulden *et al.*, 1995), kidney (Mandel *et al.*, 1995), and bladder cancer (Siemiatycki *et al.*, 1994).

Chromium Chromium has multiple oxidation states—from -2 to +6; however, the most common forms are the trivalent (III) and hexavalent (VI) forms. With regard to carcinogenicity, chromium

III does not exhibit carcinogenicity in laboratory animals whereas chromium VI has been shown to be positive for genotoxicity and carcinogenicity in a variety of bioassays (Langard, 1988; IARC, 1990). Chromium VI compounds cause genetic damage including gene mutations and DNA damage in bacteria. Several chromium VI compounds also caused mutations in yeast and insects. Many chromium VI compounds caused genetic damage in cultured human and other animal cells and in experimental animals exposed *in vivo*, including SCE, chromosomal aberrations, and cell transformation. Chromosomal aberrations, SCE, and aneuploidy were observed in workers exposed to chromium VI compounds (IARC, 1990). Chromium VI (calcium chromate, chromium trioxide, sodium dichromate, lead chromates, strontium chromate, or zinc chromates) exposure of rats following inhalation, intrabronchial, intrapleural, intratracheal, intramuscular, or subcutaneous administration resulted in benign and malignant lung tumors were observed in rats in a number of studies. In mice, calcium chromate caused benign lung tumors and chromium trioxide caused malignant lung tumors. Exposure of hamsters, guinea pigs, and rabbits to chromium (VI) compounds by intratracheal instillation did not cause lung tumors (IARC, 1980, 1990). Although the mechanisms for chromium VI carcinogenicity remain unresolved, it has been speculated that the reduction of chromium VI by glutathione is involved (Connett and Whitterhahn, 1985; Kortenkamp and O'Brien, 1994).

Hexavalent chromium (chromium VI) compounds have been classified as known human carcinogens based on data from animals studies and human epidemiological studies. Human epidemiological studies have consistently reported increased risks of lung cancer among chromate workers. Chromate workers are exposed to a variety of chromium compounds, including chromium (VI) and trivalent (III) compounds. In addition, an increased risk of a rare cancer of the sinonasal cavity was observed in these workers (IARC, 1990). Some studies suggested that exposure to chromium among workers such as chromium-exposed arc welders, chromate pigment workers, chrome platers, and chromium tanning workers may be associated with leukemia and bone cancer (Costa, 1997).

Nickel Many studies in cultured rodent and human cells have shown that a variety of nickel compounds, including both soluble and insoluble forms of nickel, exhibit genotoxicity, producing DNA strand breaks, mutations, chromosomal damage, cell transformation, and modulation of DNA repair. Soluble nickel salts can be complete carcinogens and/or initiators of carcinogenesis (Diwan *et al.*, 1992; Kasprzak *et al.*, 1990). In rats and mice, inhalation or intratracheal instillation of nickel subsulfide or nickel oxide produced dose-related increases of benign and malignant lung tumors (IARC, 1990; NTP, 1996). Inhalation of nickel compounds also caused malignant and benign pheochromocytoma in rats (NTP, 1996). Short-term intraperitoneal exposure during gestation to soluble nickel salt induced malignant pituitary tumors in the offspring. Additionally, exposure to nickel acetate through the placenta followed by exposure of the offspring to barbitol (a known tumor promoter) produces tumors of the kidney (renal cortical and pelvic tumors) (Diwan *et al.*, 1992). In adult rats, injection of soluble nickel salts followed by exposure to a promoting carcinogen resulted in kidney cancer (renal cortical adenocarcinomas) that frequently metastasized to the lung, liver, and spleen (Kasprzak *et al.*, 1990). The carcinogenic properties of metallic nickel is believed to be due to ionic nickel, which can slowly dissolve in the body from nickel compounds.

Nickel compounds are classified as known human carcinogens (11th RoC) based on animal data and sufficient evidence of

carcinogenicity from human studies. The IARC (1990, 2011) evaluation of nickel and nickel compounds concluded that nickel compounds are carcinogenic to humans based on sufficient evidence for the carcinogenicity of nickel compounds in the nickel refining industry and very strong evidence of carcinogenicity of a variety of nickel compounds in experimental studies in rodents. Several cohort studies of workers exposed to various nickel compounds showed an elevated risk of death from lung and nasal cancers (IARC, 1990). An excess risk of lung and nasal cancer was seen in nickel refinery workers exposed primarily to soluble nickel compounds (Andersen *et al.*, 1996).

Lead Lead compounds do not appear to cause genetic damage directly, but may do so through several indirect mechanisms, including inhibition of DNA synthesis and repair, oxidative damage, and interaction with DNA-binding proteins and tumor-suppressor proteins (NTP, 2003). Lead has exhibited conflicting results concerning its genotoxicity; it does not cause mutations in bacteria, but does cause chromosomal aberrations *in vitro* and *in vivo*, and causes DNA damage *in vivo* and in cell-free systems, whereas in mammalian systems, conflicting results were observed. Lead also inhibits the activity of DNA and RNA polymerase in cell-free systems and in mammalian cell cultures. Conflicting results were observed for SCE and micronucleus formation in mammalian test systems.

In studies with laboratory animals, carcinogenicity has been observed for soluble (lead acetate and lead subacetate) and insoluble (lead phosphate, lead chromate) inorganic lead compounds as well as for tetraethyl lead (an organic lead compound), following exposure via oral, injection, and in offspring exposed via the placenta or lactation. Although kidney tumors (including adenomas, carcinomas, and adenocarcinomas) were most frequently associated with lead exposure, tumors of the brain, hematopoietic system, and lung were reported in some studies (IARC, 1980; 1987, 2011; Waalkes *et al.*, 1995). Lead also appears to function as a tumor promoter, leading to increased incidence in kidney tumors initiated by *N*-ethyl-*N*-hydroxyethylnitrosamine and *N*-(4'-fluoro-4-biphenyl)acetamide (IARC, 1980, 1987). The mechanisms by which lead causes cancer are not understood.

Lead and lead compounds are classified as reasonably anticipated to be human carcinogens based on limited evidence from studies in humans and sufficient evidence from studies in experimental animals. Lead exposure has been associated with increased risk of lung, stomach, and bladder cancer in diverse human populations (Fu and Boffetta, 1995; Steenland and Boffetta, 2000; NTP, 2003). Epidemiological studies link lead exposure to increased risk for lung and stomach cancer. However, most studies of lead exposure and cancer reviewed had limitations, including poor exposure assessment and failure to control for confounding factors.

Modifiers of Chemical Carcinogenic Effects

Genetic and environmental factors have a significant impact on the way in which individuals and/or organisms respond to carcinogen exposure. As with most genes, enzymes that metabolize carcinogens are expressed in a tissue-specific manner. Within tissues, the enzymatic profile can vary with cell type or display differential localization within cells. Further, carcinogen metabolizing enzymes are differentially expressed among species. These differences may represent an underlying factor explaining the differential responses to chemical carcinogens across species.

The expression of many carcinogen metabolizing enzymes is highly inducible by foreign chemicals. Compounds such as benzo(*a*)pyrene highly induce P450 isozymes CYP1A1 and 1A2,

enzymes that display catalytic activity toward a number of polycyclic aromatics. A number of other enzymes, for example, GST isozymes, Uridine Diphosphate Glucuronyltransferases (UDPGTs) are also induced by PAHs, thus the net result is enhanced metabolism of PAHs. Numerous other chemical carcinogens are potent inducers of drug metabolizing enzymes; examples include chemicals such as phenobarbital, dichlorodiphenyltrichloroethane (DDT), ethanol, 17 β -estradiol, PPAR α agonists, each of these results in the upregulation of a distinct set of phase I and phase II enzymes. Many chemicals produce inhibitory effects on drug metabolism enzymes, and could either increase the half-life of a chemical carcinogen or prevent or delay the formation of active metabolites of carcinogens.

Polymorphisms in Carcinogen Metabolism and DNA Repair

Genetic polymorphisms arise from human genetic variability. A genetic polymorphism is when a gene has more than one allele. In assessing variability in the human genome project it was found that base variations occurred at approximately once in every 1000 base pairs. Therefore, there may be over one million genetic variations between any two individuals. A single nucleotide polymorphism (SNP) is a variant in DNA sequence found in greater than 1% of the population (Fig. 8-26). Thus, by definition, changes in DNA sequence goes from mutation to polymorphism when a unique genotype is seen in over 1% of the population. Over three million candidate SNPs have been identified to date with up to 10 million being estimated to be present within the human genome. In carcinogenesis, genetic polymorphisms may account for the susceptibility of some individuals to certain cancers. In particular, SNPs of genes involved in carcinogen metabolism (activation and detoxification) and DNA repair, have received considerable attention. A number of polymorphisms have been described in carcinogen metabolizing enzymes, with certain alleles linked to altered risk of selective cancers (Boddy and Ratain, 1997; Naoe *et al.*, 2000). Glutathione-*S*-transferases (GSTs), which are involved in detoxification of many chemical carcinogens and also in the remediation of oxidative stress, are highly polymorphic in humans. Polymorphisms of the GSTM1 phenotype have been related to bladder, gastric, and lung cancer in humans (Welfare *et al.*, 1999; Tsuchida and Sato, 1992). Individuals expressing the GSTM1 null genotype have a 1.5-fold higher risk for bladder cancer and 1.7-fold increase risk for gastric cancer compared to individuals expressing the genotype (Risch

Figure 8-26. Example of a single nucleotide polymorphism in DNA. Single nucleotide polymorphisms are instances in which a single nucleotide is changed within a DNA sequence.

et al., 2001; Ates *et al.*, 2005). The GSTM1 isoform is of particular important in carcinogenesis because this isoform exhibits the highest reactivity toward epoxides. GSTT1 isoform null individuals show a three-fold increase risk in breast cancer, a 1.6-fold increase in gastric cancer, and a four-fold increase in liver cancer compared to individuals having the genotype (Bosch *et al.*, 2006).

Similarly in women (nonsmokers) with lung cancer, a higher level of PAH DNA adducts have been detected. Higher DNA adduct levels are also found to be associated with the expression of the cytochrome P4501A1 (*CYP1A1*) gene, which bioactivates PAHs (Han *et al.*, 2003). An increase in benzo(a)pyrene DNA adduct levels correlate with increased expression of the CYP1A1. DNA repair genes, in particular oxidative DNA repair, OGG1, involved in repair of 8-OHdG-induced damage, have been linked to an increase in lung cancer in individuals with lower OGG1 expression (Goode *et al.*, 2002; Klaunig *et al.*, 2011).

In the case of prostate cancer, studies have suggested roles for a number of candidate SNPs. Recent evidence suggests that the presence of a genetic variant that is more prevalent in African American men that is less effective of clearing reactive oxygen species. Examples of candidate genes that likely contribute to prostate cancer carcinogenesis include the androgen receptor gene, steroid synthesis, and metabolism genes (*CYP17*, *CYP1B1*, *CYP3A4*, *CYP3A5*, *CYP3A43*, *SD5A2*, *HSD3B1*, *HSD3B2*, *CYP19*), transmembrane drug efflux genes (*ABCG2*), and reactive oxygen species metabolizing genes (*MnSOD*, *APE1*, *XRCC1*, *GSTP1*; Dong, 2005). Individually, polymorphisms in each of these genes have been associated with an increased risk of prostate cancer.

The importance of SNPs, cancer susceptibility, and cancer risk are illustrated in Table 8-15. If exposure to a chemical carcinogen is low and the genetic susceptibility for genes related to the carcinogenic activity is low, then the risk for cancer will also be low. If exposure to a chemical carcinogen is high but the genetic susceptibility is low, then the risk for cancer development is likely to be low. However, if the genetic susceptibility is high, then exposure to a chemical carcinogen will result in a higher risk for cancer development.

Proto-Oncogenes and Tumor-Suppressor Genes

Proto-oncogenes and tumor-suppressor genes play a key role in cancer induction. These genes encode a wide array of proteins that function to control cell growth and proliferation. Common characteristics of oncogenes and tumor-suppressor genes are shown in Table 8-16. Mutations in both oncogenes and tumor-suppressor genes contribute to the progressive development of human cancers. Accumulated damage to multiple oncogenes and/or tumor-suppressor genes can result in altered cell proliferation, differentiation, and/or survival of cancer cells (Croce, 2008; Huff, 2011).

Table 8-15

Carcinogen Exposure and Cancer Risk in Humans

EXPOSURE	SUSCEPTIBILITY (GENOTYPE)	RESULT (DISEASE)
↓	↓	Low risk
↑	↓	Low risk
↓	↑	Mod risk
↑	↑	High risk

Table 8-16

Characteristics of Proto-Oncogenes, Cellular Oncogenes, and Tumor Suppressor Genes

PROTO-ONCOGENES	ONCOGENES	TUMOR SUPPRESSOR GENES
Dominant	Dominant	Recessive
Broad tissue specificity for cancer development	Broad tissue specificity for cancer development	Considerable tissue specificity for cancer development
Germline inheritance rarely involved in cancer development	Germline inheritance rarely involved in cancer development	Germline inheritance frequently involved in cancer development
Analogous to certain viral oncogenes	No known analogues in oncogenic viruses	No known analogues in oncogenic viruses
Somatic mutations activated during all stages of carcinogenesis	Somatic mutations activated during all stages of carcinogenesis	Germline mutations may initiate, but mutation to neoplasia occurs only during progression stage

Retroviruses Evidence that specific genes (oncogenes) could cause cancer first came from studies showing sarcomas could be produced in healthy chickens by injecting them with cell-free extracts derived from chicken tumors (Rous, 1911). The transforming agent in the filtrate eventually was shown to be an RNA-type tumor virus, the *Rous sarcoma virus* (RSV) that is capable of transforming a normal cell and produce sarcomas within weeks of injection (Temin and Rubin, 1958). The genome of RSV and other retroviruses consists of two identical copies of mRNA, which is then reverse transcribed into DNA and incorporated into the host-cell genome. Oncogenic transforming viruses such as RSV contain the *v-src* gene, a gene required for cancer induction. It was later demonstrated that normal cells from chickens and other species contain a gene closely related to *v-src* in RSV; the normal “proto-oncogene” commonly is distinguished from the viral gene by the prefix “c” (*c-src*; Oppermann *et al.*, 1979). This discovery showed that cancer may be induced by the action of normal, or nearly normal, genes.

DNA Viruses Six major classes of DNA tumor viruses have been identified: simian virus 40 (SV40), polyoma virus, hepatitis B virus, papilloma viruses, adenoviruses, herpes viruses, and poxviruses. Unlike retroviral oncogenes, which are derived from normal cellular genes and have no function for the virus, the known oncogenes of DNA viruses are integral parts of the viral genome required for viral replication. SV40 or polyoma viruses are not capable of inducing tumors in their natural host species (monkey and mice, respectively). Infection by small DNA viruses is lethal to most non-host animal cells; however, a small proportion integrates the viral DNA into the host-cell genome. The cells that survive infection become permanently transformed due to the presence of one or more oncogene in the viral DNA. For example, SV40 codes for the large T antigen, which alone is capable of inducing transformation (Fried and Prives, 1986). Both SV40 and polyoma viruses use the host-cells DNA synthetic apparatus for their own replication. Papilloma viruses can infect and cause tumors

in rabbits, cows, and humans (Lancaster and Olsen, 1982). Of the human papilloma viruses, types 6, 10, and 11 are associated with genital warts whereas types 16, 18, 31, and 33 are associated with human cervical cancers (Vousden, 1989). Herpes viruses are complex and are capable of producing tumors in frogs, chickens, monkeys, and humans (Rapp, 1974). Included among this class is the Epstein–Barr virus, a causative agent in the development of Burkett B-cell lymphomas and in nasopharyngeal carcinoma (de-Thé *et al.*, 1978), and is mediated by genes encoding *EBNA-1*, *EBNA-2*, and *latent membrane protein* (Fahreus *et al.*, 1990). Adenoviruses affect host and non-host cells differently; in host cells, infection causes lysis whereas in non-host cells, infection results in transformation via *E1A* and *E1B* genes (Pettersson and Roberts, 1986). Hepatitis B viruses specifically infect the liver of ducks, woodchucks, and squirrels, and are strongly associated with liver cancer development in humans; infected individuals exhibit a >100-fold risk for cancer development (Synder *et al.*, 1982). Hepatitis B gene X is thus far the main gene implicated in the transformation process (Kim *et al.*, 1991). Poxviruses (eg, Yaba monkey virus, Shope fibroma virus), replicate in the cytoplasm of infected cells and produce benign tumors (Niven *et al.*, 1961).

Proto-Oncogenes An oncogene is a gene encoding a protein that is capable of transforming cells in culture or inducing cancer in animals. Of the known oncogenes, the majority appear to have been derived from normal genes (ie, proto-oncogenes), and are involved in cell signaling cascades (Table 8-17). Because most proto-oncogenes are essential for maintaining viability, they are highly conserved evolutionarily. It has been clearly demonstrated that altered expression of these genes results in unregulated control of cell growth. Activation of proto-oncogenes arises through mutational events occurring within proto-oncogenes (Alitalo and Schwab, 1986; Bos, 1989). It has been recognized that a number of chemical carcinogens are capable of inducing mutations in proto-oncogenes (Balmain and Pragnell, 1983).

Several oncogene products are associated with growth factors. The *sis* oncogene encodes for platelet-derived growth factor (PDGF), which consists of type A and B chains. Active PDGF can consist of homo- or heterodimers of the A and B chains. Only cells that express the PDGF receptor are susceptible to transformation by the *sis* oncogene (Dooliter *et al.*, 1983). Fibroblast growth factor (FGF), epidermal growth factor (EGF), and the *wnt* family also have oncogenes that encode for their production (Burgess *et al.*, 1989; Nusse and Varmus, 1992). Enhanced expression of these growth factor genes leads to transformation of cultured cells. In addition, lung carcinomas and astrocytomas in humans express both PDGF and its receptor.

In order for the growth factors listed above to induce cell growth, the cell must also express the appropriate growth factor receptors. Ligand binding to receptors in many cases results in the activation of signaling cascades, of which a number have protein kinase activity. Protein kinases can phosphorylate at tyrosine, serine, or threonine residues. Several oncogene products have been identified that have tyrosine kinase activity (eg, *src*, *fps*, *fgr*, *fms*, *kit*, and *ros*; Collett and Erikson, 1978). Growth factor receptors including EGF, PDGF, insulin, insulin-like growth factor, and FGF have tyrosine activity (Wells, 1999). An extensive number of protein kinases are serine or threonine kinases, some of which can be activated in tumor cells and lead to transformation. The protein kinase C family consists of serine/threonine kinases (Nishizuka, 1988). This family of proteins participates in the inositol–phospholipid second messenger pathway and can be activated by calcium and diacylglycerol, and phorbol ester tumor promoters. The *raf* and

mos oncogenes are other example of serine threonine kinases, that interact with mitogen activated kinase pathways, leading to enhance the expression of “immediate-early” genes such as *Myc*, and *Fos/Jun* heterodimers, and ultimately leads to enhanced cell growth (Su and Karin, 1996).

Guanine nucleotide binding proteins is a subset of the Guanosine-5'-triphosphate (GTP) superfamily. The primary oncogenic members of this family are the *ras* genes (eg, *Ha-*, *Ki-*, and *n-ras*), which were initially found in murine retroviruses, and are frequently activated in human tumors and in chemically induced tumors in rodent models (McCormick, 1994). The three *ras* forms differ by only 20 amino acids and have a conserved cytosine-186, which is a site for posttranslational modification by a farnesyl, isoprenyl group, a modification that is needed for membrane localization (Hancock *et al.*, 1989). Mutations in *ras* affect the association of the Ras with GTP, and because Ras is active when GTP is bound, constitutive Ras activation is often seen with mutated forms of *ras*. Many mutation sites are associated with activation of *ras* and include codons 12, 13, 61, 116, 117, 119, and 146 (de Vos *et al.*, 1988). Although a dominant gain-of-function mutation in the *ras* gene converts it into an oncogene, a recessive loss-of-function mutation in the *NF1* gene also leads to constitutive Ras activation. *NF1* encodes a GTPase-activating enzyme (GAP) that accelerates

hydrolysis of GTP and the conversion of active GTP-bound Ras to inactive GDP-bound Ras. The loss of GAP leads to sustained Ras activation of downstream signal transduction proteins. Individuals with neurofibromatosis have inherited a single mutant *NF1* allele; subsequent somatic mutation in the other allele leads to formation of neurofibromas.

In addition to acting at the receptor level, some oncogene products are nuclear transcription factors and thus cause alteration of gene expression. One of the first to be identified was the *erbA* oncogene product, which is an altered form of the thyroid hormone receptor (Damm *et al.*, 1989). This altered form is unable to bind thyroid hormone and allows the oncogene protein to act in a dominant-negative manner, functioning as a constitutive repressor of normal expression of genes regulated by thyroid hormone. Another family of oncogenes encode for the AP-1 transcription factor, a complex consisting of *jun* and *fos*, as well as Jun family members with homology to c-jun (Jun B and Jun D) (Chiu *et al.*, 1988; Vogt, 2001). Phorbol esters and several other tumor-promoting compounds are able to rapidly induce gene expression of both *fos* and *jun*. Activation of both *fos* and *jun* results in the constitutive expression of the transcription factors and sustained stimulation of cell growth signals. The *myc* family (*c-myc*, *N-myc*, and *L-myc*) encode for transcription factors that are found activated in a number of tumor types (Marcu *et al.*, 1992).

Tumor-Suppressor Genes

Retinoblastoma (*Rb*) Gene In contrast to oncogenes, the proteins encoded by most tumor-suppressor genes act as inhibitors of cell proliferation or cell survival (Table 8-18). The prototype tumor-suppressor gene, *Rb*, was identified by studies of inheritance of retinoblastoma. Loss or mutational inactivation of *Rb* contributes to the development of a wide variety of human cancers. In its unphosphorylated form, *Rb* binds to the *E2F* transcription factors preventing *E2F*-mediated transcriptional activation of a number of genes whose products are required for DNA synthesis. In addition, the *Rb*-*E2F* complex acts as a transcriptional repressor for many of these same genes (Chellappan *et al.*, 1991). During the early G_1 phase of the cell cycle, *Rb* is an unphosphorylated state, but becomes phosphorylated during late G_1 , causing dissociation from *E2F*—a process that allows *E2F* to induce synthesis of DNA replication enzymes, resulting in a commitment into the cell cycle. *Rb* phosphorylation is initiated by an active Cdk4–cyclin D complex and is completed by other cyclin-dependent kinases (Weinberg, 1995; Sherr, 1993). Most tumors contain an oncogenic mutation of one of the genes in this pathway such that cells enter the S phase of the cell cycle in the absence of the proper extracellular growth

signals that regulate Cdk activity. In addition, *Rb* is bound and inactivated by the E1A protein of the adenoviruses (Whyte *et al.*, 1988) and also by the large T antigen of SV40 and the E7 protein of the papilloma virus, suggesting that the elimination of *Rb* function may be an important mechanism in tumor development by viruses and/or mutations induced by chemical carcinogens.

***p53* Gene** The *p53* protein is a tumor-suppressor gene that is essential for the checkpoint control and arrests the cell cycle in cells with damaged DNA in G_1 . Cells with functional *p53* arrest in G_1 when exposed to DNA-damaging agents such as irradiation, whereas cells lacking functional *p53* are unable to block the cell cycle. *p53* is activated by a wide array of stressors including UV light, γ irradiation, heat, and several carcinogens. DNA damage by γ irradiation or by other stresses leads to the activation of certain kinases, including ataxia telangiectasia mutated (*ATM*), which is encoded by the gene mutated in ataxia telangiectasia and a DNA-dependent protein kinase. Phosphorylation of *p53* by these and other kinases results in stabilization of *p53* and an increase in cell content of this protein (Finlay *et al.*, 1989). The active form of *p53* is a tetramer of four identical subunits. A missense point mutation in one *p53* of the two alleles in a cell can abrogate almost all *p53* activity because virtually all the oligomers will contain at least one defective subunit and such oligomers cannot function as a transcription factor. Oncogenic *p53* mutations thus act as “dominant negatives,” in contrast to tumor-suppressor genes such as *Rb*.

Virtually all *p53* mutations abolish its ability to bind to specific DNA sequences and activate gene expression (El-Deiry *et al.*, 1992). The transcription of cyclin-kinase inhibitor *p21*, which binds to and inhibits mammalian G_1 Cdk–cyclin complexes, is induced by *p53*. As a result, cells with damaged DNA are arrested in G_1 until the damage is repaired and the levels of *p53* and *p21* fall; the cells then can progress into the S phase. In most cells, accumulation of *p53* also leads to induction of proteins that promote apoptosis, and, therefore, would prevent proliferation of cells that are likely to accumulate multiple mutations. When the *p53* checkpoint control does not operate properly, damaged DNA can replicate, producing mutations and DNA rearrangements that contribute to the development of transformed cells. Proteins that interact with and regulate *p53* are also altered in many human tumors. The gene encoding one such protein, *MDM2*, is amplified in many sarcomas and other human tumors that maintain functional *p53* (Leach *et al.*, 1993). Under normal conditions, *MDM2* binds the N-terminus of *p53*, repressing the ability of *p53* to activate transcription of *p21* and genes mediating *p53* degradation. Thus, *MDM2* normally inhibits the ability of *p53* to block at G_1 or induce apoptosis. Enhanced *MDM2* levels in tumor cells therefore results in decreased functional *p53* and prevents *p53* from growth arrest in response to irradiation or chemical carcinogens. For example, benzo(*a*)pyrene produces inactivating mutations at codons 175, 248, and 273 of the *p53* gene in cultured cells; these same positions are mutational hot spots in human lung cancer (Hollstein *et al.*, 1991). Aflatoxin exposure induces a G to T transversion at codon 249 of *p53*, and methyl-*N*'-nitro-*N*-nitrosoguanidine (MNG) can alter methylation of DNA leading to inactivation of *p53* (Bressac *et al.*, 1991).

***BRCA1* Gene** Genetic analysis of breast tumors has revealed a hereditary predisposition for breast cancer linked to *BRCA1*, a tumor-suppressor gene. Mutation of a single *BRCA1* allele results in a 60% probability of developing breast cancer by age 50. In families transmitting the mutant *BRCA1* allele, the normal allele is often absent in tumors. A number of investigators have shown that germ line mutations lead to loss of function of the *BRCA1* gene, perhaps by acting as a transcription factor through binding at a zinc

Table 8-18

Examples of Tumor Suppressor Genes and Cancer Association

TUMOR SUPPRESSOR	DISORDER	NEOPLASM
Rb1	Retinoblastoma	Small-cell lung carcinoma
p53	Li–Fraumeni syndrome	Breast, colon, lung cancers
BRCA1	Unknown	Breast carcinoma
WT-1	Wilms tumor	Lung cancer
p16	Unknown	Melanoma

finger domain. However, no mutations have been observed in sporadic breast cancers (Futreal *et al.*, 1994), suggesting that *BRCA1* gene silencing may occur through nonmutational mechanisms.

Wilms Tumor Gene (*WT1*) Wilms tumor occurs in the developing kidney at a rate of approximately one per 10,000 children. The *WT1* gene is believed to be responsible for tumor development and is thought to function as a transcription factor (Hastie, 1994). The DNA-binding region of the *WT1* gene contains four zinc finger domains, and binds a consensus sequence shared with EGR1; however, *WT1* acts as a transcriptional repressor at this site (Rauscher *et al.*, 1990). Similar to *p53*, *WT1* mutant alleles act in a dominant-negative manner.

***p16* Gene** The group of proteins that function as cyclin-kinase inhibitors play an important role in cell cycle regulation. Mutations, especially deletions of the *p16* gene, that inactivate the ability of p16 to inhibit cyclin D-dependent kinase activity are common in several human cancers including a high percentage of melanomas (Kamb *et al.*, 1994). Loss of p16 would mimic cyclin D1 overexpression, leading to Rb hyperphosphorylation and release of active E2F transcription factor. Thus, p16 normally acts as a tumor suppressor. As with the *BRCA1* gene, relatively few mutations have been found in this gene, and some researchers have speculated that epigenetic mechanisms such as gene silencing by DNA methylation may occur during tumorigenesis (Merlo *et al.*, 1995).

Hormesis, Dose Response, and Carcinogenesis

Hormesis is defined as a dose-response curve in which a U, J, or inverted U-shaped dose-response is observed, with low-dose exposures often resulting in beneficial rather than harmful effects (Calabrese, 2002) (Fig. 8-27). One of the first reports establishing a hormetic response was observed with ionizing radiation, in which it was hypothesized to be due to adaptation to background radiation exposure, as well as enhanced metabolism and detoxification (Calabrese, 2002; Parsons, 2003). Numerous examples exist that provide evidence for U- and J-shape dose relationships to different biomarkers of carcinogenesis, both for initiating and promoting carcinogens. For example, low-dose styrene treatment resulted in a decrease of chromosomal aberrations (Camurri *et al.*, 1983). A reduction in DNA strand breaks in human keratinocytes was seen following low-dose exposure to *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine, whereas high doses were greatly elevated compared to controls (Kleczkowska and Althaus, 1996). Several chronic bioassays for carcinogenicity in rats and mice have demonstrated a negative correlation between proliferative hepatocellular lesions and lymphomas at low- and medium-dose levels (Young and Gries, 1984). TCDD at hepatocarcinogenic doses resulted in a dose-dependent reduction in mammary and uterine tumors (Kociba *et al.*,

Figure 8-27. Hormesis curve.

1978). TCDD also reduces tumor incidence after exposure to low doses of radiation and selenium (Pollycove *et al.*, 2001; Nordberg *et al.*, 1981). Evidence for a U-shaped dose-response curve has also been demonstrated for phenobarbital (Kitano *et al.*, 1998; Ito *et al.*, 2003; Kinoshita *et al.*, 2003). These investigators have shown that phenobarbital promoted the growth of diethylnitrosamine-induced hepatic lesions at doses between 60 and 500 ppm, whereas doses between one and 7.5 ppm decreased lesion growth, hepatocellular carcinoma, and tumor multiplicity.

Adaptive responses have been proposed to explain the hormetic effects observed by chemical carcinogens. When experimental animals are exposed to chemicals, the initial response is an adaptive response to maintain homeostasis (Calabrese, 2002). Adaptive responses usually involve actions of the chemical on cellular signaling pathways that lead to changes in gene expression, resulting in enhanced detoxification and excretion of the chemical as well as preserving the cell cycle and programmed cell death. It has been proposed that following very low doses of chemicals, the upregulation of these mechanisms overcompensates for cell injury such that a reduction in tumor promotion and/or tumor development is seen, and would explain the U- or J-shaped response curves obtained following carcinogen exposure.

A common feature of chemical carcinogens for which hormetic effects have been proposed is the formation of reactive oxygen species and the induction of cytochrome P450 isoenzymes. Inhibition of carcinogenesis by low levels of phenobarbital has been postulated to involve the suppression of 8-OHdG generation and cellular proliferation within areas of glutathione-*S*-transferase pi (GST-P) positive foci, possibly related to enhanced expression of the gene encoding the enzyme oxoguanine glycosylase one (Ogg1), which is responsible for the repair of 8-OHdG lesions (Kinoshita *et al.*, 2003). Another explanation for the suppressive effect of low-level phenobarbital on the development of preneoplastic lesions involves the stimulation of hepatic drug metabolizing enzymes, which detoxify carcinogens (Pitot *et al.*, 1987). In a low-dose phenobarbital study, cDNA microarray analysis resulted in a suppression of mRNA expression of MAP kinase p38, JNK1, 2, and other intracellular kinases (Kinoshita *et al.*, 2003). Thus, suppression of signal transduction modulators appears to be involved in the inhibitory effect of phenobarbital on cell proliferation.

Chemoprevention

The study of chemicals that prevent, inhibit, or slow down the process of cancer is referred to as chemoprevention. A number of chemicals, including drugs, antioxidants, foodstuffs, and vitamins have been found to inhibit or retard components of the cancer process (Table 8-19) in both in vitro and in vivo models (Stoner *et al.*, 1997). Cancer chemopreventive chemicals may function at one or more of the steps in the carcinogenesis process. Cancer chemoprevention involves the administration or inclusion in the diet of natural or synthetic chemicals in an attempt to prevent, halt, or reverse the process of carcinogenesis. A basic assumption in chemoprevention is that treating early stages of the malignant process will halt or delay the progression to neoplasia. Chemopreventive chemicals may function via one or several mechanisms; inhibitors of carcinogen formation, blocking agents, and/or as suppressing agents (Table 8-19). Blocking agents serve to prevent the metabolic activation of genotoxic or nongenotoxic carcinogens by either inhibiting its metabolism or enhancing the detoxification mechanisms. In the case of reactive oxygen species generation by a carcinogen, antioxidants, such as *N*-acetylcysteine, or vitamins E, A, and C serve as blocking agents by trapping the oxidative species before it can induce cellular

Table 8-19

Classes of Chemopreventive Agents

INHIBITORS OF CARCINOGEN FORMATION	EXAMPLES
Reductive acids	Ascorbic acid
Phenols	Cafeic acid, ferulic acid, gallic acid
Sulfhydryl compounds	<i>N</i> -Acetylcysteine
Amino acids	Praline, thioproline
Blocking Agents	
Inhibition of cytochrome P450	Dithiocarbamates, ellagic acid, diallyl sulfide, isothiocyanates
Induction of cytochrome P450	Indole-3-carbinol, β -naphthoflavone
Induction of phase II enzymes	
Glutathione S-transferase	Allyl sulfides, dithiolethiones, isothiocyanates
UDP-glucuronyltransferase	Polyphenols
Glutathione peroxidase	Selenium
Scavenge electrophiles	Ellagic acid, <i>N</i> -acetylcysteine
Scavenge free radicals	Sodium thiosulfate, polyphenols, vitamin E
Increase overall levels of DNA repair	Vanillin
Increase poly(ADP-ribosyl) transferase	<i>N</i> -Acetylcysteine
Suppress error-prone DNA repair	Protease inhibitors
Suppressing Agents	
Inhibit polyamine metabolism	DRv10, polyphenols, substituted putrescines
Induce terminal cell differentiation	Calcium, retinoids, vitamin D ₃
Modulate signal transduction	Glycyrrhetic acid, nonsteroidal anti-inflammatory drugs (NSAIDs), polyphenols, retinoids
Modulate hormonal/growth factor activity	
Inhibit oncogene activity	NSAIDs, retinoids, tamoxifen
Promote intracellular communication	Genistein, NSAIDs, monoterpenes
Restore immune response	Carotenoids, polyphenols, retinoids
Induce apoptosis	NSAIDs, selenium, vitamin E
Correct DNA methylation imbalances	Butyric acid, genistein, selenium, sulindac sulfone, retinoids
Inhibit basement membrane degradation	Folic acid, choline, methionine
Inhibit arachidonic acid metabolism	Protease inhibitors
	Glycyrrhetic acid, <i>N</i> -acetylcysteine, NSAIDs, polyphenols

damage. The drug oltipraz induces phase two enzymes; in particular, glutathione-S-transferase has been shown to reduce the carcinogenicity of aflatoxin B1 by enhancing its detoxification (Jacobson *et al.*, 1997). Chemopreventive chemicals increase tissue resistance function on the target tissue, usually an early preneoplastic lesion by increasing tissue maturation and/or decreasing cell proliferation. Suppressing agents induce tissue differentiation, may counteract oncogenes, enhance tumor-suppressor gene activities, inhibit proliferation of premalignant cells, or modify the effect of the carcinogen on the target tissue. Retinoic acid is a classic agent that functions by inducing target tissue differentiation. Similarly, viral vectors containing wild-type p53 have been shown to negate the effects of tumor growth driven via p53 mutation. Extensive experimental evidence exists showing the inhibition or retarding of the cancer process by chemopreventive chemicals. These studies have been performed in animal models and cell systems. Although the human results of chemoprevention interventions are less convincing than the experimental models, considerable epidemiological evidence demonstrates an inverse relationship of some nutrient factors with cancer risks.

ASSESSING CARCINOGENICITY OF CHEMICALS

A number of *in vivo* and *in vitro* experimental systems are available to assess the potential carcinogenicity of chemicals. The types of tests available to identify chemicals with carcinogenic potential can be classified into general categories, based on the duration required

to conduct the test (Table 8-20). Short-term tests are typically of the duration of days to a few weeks, intermediate-term tests last from weeks up to a year, whereas chronic long-term tests usually encompass six months to two years exposure to a chemical. These bioassays use bacterial and mammalian targets.

Short-Term Tests for Mutagenicity

Short-term tests for mutagenicity were developed to identify potentially carcinogenic chemicals based on their ability to induce mutations in DNA either *in vivo* or *in vitro*. A variety of

Table 8-20

General Methods for Identification of Potential Carcinogens

METHOD	TIME FRAME
Short term	
Mutagenesis assays	Several weeks
Transformation in cell culture	1–3 months
Medium term	
Qualitative and quantitative analysis of preneoplasia	2–8 months
Long term	
Chronic bioassay in animals	18–24 months

Primary DNA damage		
DNA repair in vivo or in vitro	Unscheduled DNA synthesis and/or DNA strand breaks	Furihata and Matsushima (1987)
Rodent liver: unscheduled DNA synthesis induction	Unscheduled DNA synthesis in rodent cells in vivo and/or in vitro	Kennelly (1995) Steinmetz <i>et al.</i> (1988)

in vivo and in vitro short-term tests are available to test the potential carcinogenicity of a chemical (Table 8-21). The majority of these tests measure the mutagenicity of chemicals as a surrogate for carcinogenicity. Therefore, although they are usually very predictive of indirect acting and direct acting (if a metabolic source is provided), these tests routinely fail to detect nongenotoxic carcinogens.

In Vitro Gene Mutation Assays The most widely used short-term test is the Ames assay (Ames *et al.*, 1975; Mortelmans and Zeiger, 2000). The relative simplicity and low cost of the test make it a valuable screening tool for mutagenic carcinogens. *Salmonella typhimurium* strains, deficient in DNA repair and unable to synthesize histidine, are used. In the presence of a mutagenic chemical, the defective histidine gene can be mutated back to a functional state (*back mutation*), resulting in a restoration of bacterial growth in medium lacking histidine. The mutant colonies, which can make histidine, are referred to as “revertants.” The Ames test in basic form can detect direct but not indirect genotoxic carcinogens. With the inclusion of a metabolic source, specifically the 9000g supernatant (S9) of a rat liver homogenate to promote metabolic conversion

of the chemical, the Ames can also detect indirect-acting genotoxic carcinogens. Fig. 8-28 describes the standard method used for performing the Ames assay.

Genetically unique strains of the *S typhimurium* bacterium have been developed for determining specific mutational targets. Strains TA100 and TA1535 are able to detect of point mutations whereas strains TA98, TA1537, and TA1538 are able to detect frame shift mutations. Chemicals are typically tested at several concentrations (usually five or more) and the mutation frequency (number of revertants) is calculated. Activation-independent (eg, sodium azide, methyl methanesulfonate) and activation-dependent (eg, 2-aminoanthracene) positive controls are included in each assay.

The mouse lymphoma assay is a mutagenicity assay used to determine whether a chemical is capable of inducing mutation in eukaryotic cells. Typically, mouse lymphoma L5178Y cells are used, and the ability of the cell cultures to acquire resistance to trifluorothymidine (the result of forward mutation at the thymidine kinase [TK] locus) is quantified. Another mammalian cell mutation assay, the Chinese hamster ovary (CHO) test, is also commonly used to assess the potential mutagenicity of chemicals. This assay uses the hypoxanthine–guanine phosphoribosyltransferase

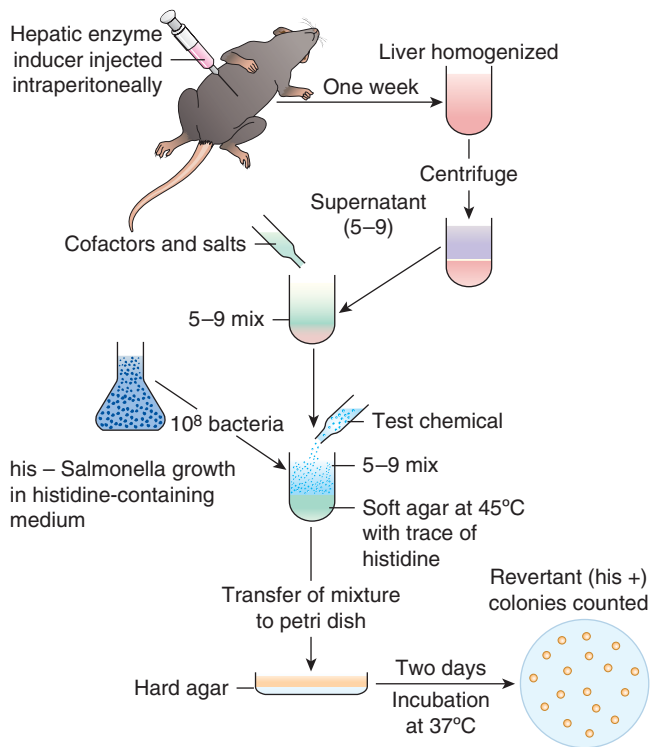

Figure 8-28. Scheme of the Ames test for mutagenesis of chemicals in *Salmonella* bacterial strains.

(HGPRT) gene as the endpoint. The basis for these assays is shown in Fig. 8-29. Cells are treated with the test chemical and then placed into suspension with selective medium for replication and fixation of induced mutations. Cells are then plated for colony growth, and after several days, colony numbers and colony size are recorded. The number of mutant colonies is a measure of the ability of the test chemical to induce a genetic change at the TK or HGPRT loci in these transformed cells.

As with the Ames assay, these assays are frequently performed in the presence of an exogenous metabolic source (eg, irradiated epithelial cell feeder layer). Because not all carcinogens are mutagens and/or directly damage DNA, the concordance with the chronic in vivo bioassay for these mutagenicity assays is relatively low. For a historical perspective on the utilization of the Ames/Salmonella assay, a recent review by Claxton *et al.* (2010) provides more information on the use of the assay and the role of metabolic activation and mutagenicity testing with respect to genotoxic carcinogens.

In Vivo Gene Mutation Assays For the assessment of the carcinogenic potential of chemicals in vivo genotoxicity tests are important complement to in vitro mutagenicity tests. The in vivo tests have advantages over the in vitro test systems in that they take into account whole animal processes such as absorption, tissue distribution, metabolism, and excretion of chemicals and their metabolites. The commonly used in vivo models include transgenic rodent mutation assay systems based on the genes of the *lac* operon, MutaMouse (Gossen *et al.*, 1989) and Big Blue (Kohler *et al.*, 1991a,b). Some details of the *lac* operon are shown in Fig. 8-30).

The MutaMouse is a transgenic mouse in which a vector prepared from bacteriophage λ DNA (λ gt10) has been stably inserted

Mammalian cell line used for gene mutation studies

Mouse lymphoma L5178Y	TK, HGPRT
CHO	HGPRT
V79 hamster cells	HGPRT

Selection of forward mutations by loss of HGPRT + phenotype in V79 or chinese hamster ovary cells.

Performed in the presence of an activation system or hepatic feeder layer

Selection of mutagen-induced TK $-/-$ phenotype in TK $+/-$ in mouse lymphoma assay (MOLY) in L5178Y cells. This assay detects forward mutations at the TK locus.

Treat TK ($+/-$) cells with test compound. Fluoruracil is converted to a toxin, killing the cells. If mutation in TK occurs, FU is not metabolized to a toxin and colonies grow.

Figure 8-29. Outline of chemically induced mutation in mouse cell lines with TK or HGPRT as the target gene.

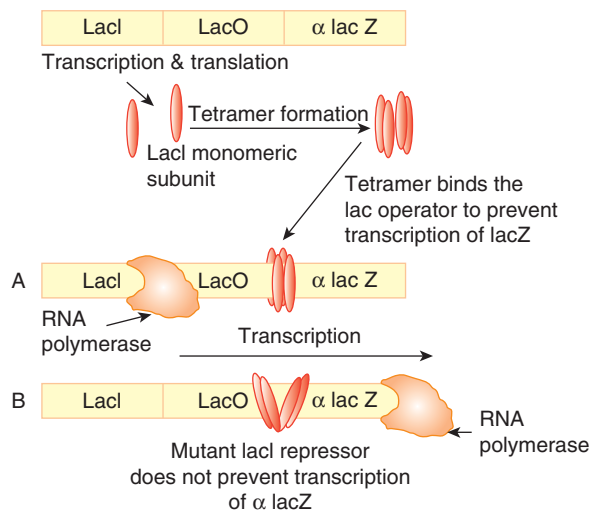

Figure 8-30. Schematic representation of the *lac* operon in *E. coli*.

into the genome and exists within every cell. Within the λ DNA sequence, the bacterial gene *lacZ*, which encodes for β -galactosidase, was inserted at the single *EcoRI* restriction site. The entire vector contains ~47,000 bp, of which the *lacZ* gene comprises 3126 bp. The construction and analysis of MutaMouse have been previously described (Gossen *et al.*, 1989). The Big Blue transgenic mouse was developed using a 47.6-kb λ shuttle vector containing the bacterial *lacI* gene (1080 bp), which encodes the repressor protein of the *lacZ* gene. As with the MutaMouse, this vector is stably inserted into the genome and exists in every cell. Details on the Big Blue system are described elsewhere (Kohler *et al.*, 1991a,b).

To detect mutations, following exposure of mice to test chemicals, mutations are analyzed in high molecular DNA isolated from the tissue under investigation. The next step is to isolate a viable λ phage for the analysis of mutations in the *lacZ* or *lacI* genes from the mouse. The infectious λ particles are detected as plaques that form on a bacterial (*Escherichia coli* strain) lawn grown on an agar surface. In the case of MutaMouse a positive selection system is used that involves the scoring of clear plaques on titration plates to determine the total number of plaque forming units and on selection plates to determine the number of mutants (Gossen and Vijg, 1993). For Big Blue, a nonselectable color screening assay is used, scoring blue mutant plaques among the nonmutant clear plaques (Kohler *et al.*, 1991a). In each case the ratio of mutants to the total population provides a mutation frequency for each chemical and each organ tested. As with the other short-term tests that have been discussed, it is unlikely that *in vivo* genotoxicity test systems will identify nongenotoxic/non-DNA-reactive compounds.

Chromosomal Alterations Chromosomal alterations are quite common in malignant neoplasms, as such, the detection of chromosomal abnormalities by test chemicals is considered an excellent test for the assessment of carcinogenic potential. Both *in vivo* and *in vitro* assays are available to assess chromosomal alterations. In mammalian cell lines, most of the test systems used the same lines as used in the mutation assay. To assess induction of chromosomal alterations, cells are harvested in their first mitotic division after the initiation of chemical exposure. Cells are stained with Giemsa, and scored for completeness of karyotype (21 ± 2 chromosomes). The classes of aberrations recorded include breaks and terminal deletions, rearrangements and translocations, as well as despiralized chromosomes, and cells containing 10 or more aberrations.

SCEs are a measure of DNA damage and increased levels of DNA damage, events that are associated with mutation induction and cancer. During metaphase, sister chromatids, each encompassing a complete copy of one chromosome, are bound together through specific protein interactions. SCEs are a reflection of an interchange of DNA between different chromatids at homologous loci within a replicating chromosome (Latt *et al.*, 1981). Differential staining of chromatids is therefore used to assess SCEs. Typically, 5-bromodeoxyuridine (BrdU) is added along with the test chemical for one cell replication followed by replacement of the medium with medium containing BrdU and colcemid, without test chemical. Cells are then harvested, stained and second-division metaphase cells scored to determine the frequency of SCE/cell for each dose level.

In vivo, analysis of chromosomal alterations has been described since the 1980s (Sasaki, 1980). Disruption of the DNA replication process or damage to chromosomes by chemicals can alter the genetic material distributed to either of the two daughter nuclei. When this occurs, the genetic material that is not incorporated into a new nucleus may form its own "micronucleus," which is clearly visible with a microscope. For this assay, animals are exposed to chemicals and the frequency of micronucleated cells is determined at some specified time after treatment. Micronucleus tests must be performed on cells that are dividing, most typically in cells from bone marrow samples (Heddle *et al.*, 1983). As with other short-term tests, the micronucleus test provides complementary information to gene mutation data but neither tests enhance the ability to detect genotoxic carcinogens, nor is capable of detecting non-DNA-reactive carcinogens. However, this assay does provide information on the ability of a chemical to disrupt mammalian chromosome structure and function.

DNA Damage Primary DNA damage represents possible pre-mutational events that can be detected, either directly or indirectly, by a number of techniques using mammalian cells in culture or using rodent tissue. Unscheduled DNA synthesis (UDS) is a commonly used assay that measures the ability of a test article to induce DNA lesions by measuring the increase in DNA repair. Among the available techniques is the measurement of DNA strand breaks both *in vivo* and *in vitro* (Miyamae *et al.*, 1997). Although a wide array of assays are available to assess DNA damage, the Comet assay, or single cell gel electrophoresis, has become one of the standard methods for assessing DNA damage and repair at the individual cell level. Since its introduction 1988, the alkaline comet assay has been modified to increase the utility of this technique for detecting various forms of DNA damage (eg, single- and double-strand breaks, oxidative DNA base damage, and DNA-DNA/DNA-protein/DNA-Drug cross-linking) and DNA repair in virtually any eukaryotic cell. Through the use of lesion-specific endonucleases, the levels of UV-induced pyrimidine dimers, oxidized bases, and alkylation damage can be assessed in biological samples (Collins, 2004).

Short-Term Tests: Transformation Assays A variety of *in vitro* test systems have been developed to assess the carcinogenic potential of chemicals. The C3H/10T $\frac{1}{2}$ cell line has been widely used for the transformation assay. It was originally derived from fibroblasts taken from the prostate of a C3H mouse embryo. The cells are approximately tetraploid but the chromosome number in the cells varies widely. As such, these cells are chromosomally abnormal and have already passed through some of the stages that might be involved in the production of a cancerous cell. Upon plating these cells, they will stop growing when their density is

sufficiently high (contact growth inhibition). However, the contact inhibition can fail, resulting in cell piling forming a transformed colony. Therefore, following exposure to xenobiotics, this assay assesses carcinogenic potential based on the percentage of colonies that are transformed (Reznikoff *et al.*, 1973).

The most frequently used endpoint for cell transformation is morphological transformation of mammalian cell fibroblasts in culture. Transformation assays using BALB3T3 and Syrian hamster embryo (SHE) cells are available for the assessment of the carcinogenic potential of chemicals. BALB/3T3 transformation assay, however, has not gained full acceptance as a carcinogenic screening assay mainly due to issues regarding its relatively low sensitivity, low reproducibility and relatively long test period (Sakai and Sato, 1989; Schechtman, 1985). The SHE cell assay, a diploid cell transformation assay, measures carcinogenic potential of xenobiotics by assessing transformed colonies based on morphological criterion. The SHE cell assay has several features that make this an appealing method to evaluate the carcinogenic potential of xenobiotics: (1) The assay has a >85% concordance with the two-year rodent bioassay; (2) the stages involved in the clonal transformation of SHE cells (eg, morphological transformation, immortalization, and tumorigenicity) closely resemble those associated with the classic defined stages of carcinogenesis (eg, initiation, promotion and progression); and (3) non-genotoxic/non-DNA-reactive carcinogens elicit a positive response on morphological transformation in the SHE cell assay (Barrett and Lamb., 1985; LeBoeuf *et al.*, 1990; Isfort *et al.*, 1994, 1996). The SHE assay offers an alternative, regulatory approved, means to check the validity of the positive result before embarking on potentially unnecessary and expensive chronic or subchronic testing protocols.

Chronic Testing for Carcinogenicity

The majority of in vivo carcinogenicity testing is performed in rodent models. The administration of chemicals in the diet, often for extended periods, for assessment of their safety and/or toxicity

began in the 1930s (Sasaki and Yoshida, 1935). Animal testing today remains a standard approach for determining the potential carcinogenic activity of xenobiotics. In addition to the lifetime exposure rodent models, organ-specific model systems, multistage models, and transgenic models are being developed and used in carcinogen testing (Table 8-22).

Chronic (Two Year) Bioassay Two-year studies in laboratory rodents remain the primary method by which chemicals or physical agents are identified as having the potential to be hazardous to humans. The most common rodents used are the rat and mouse. Typically the bioassays are conducted over the lifespan of the rodents (two years). Historically, selective rodent strains have been used in the chronic bioassay; however, each strain has both advantages and disadvantages. For example, the NTP typically uses Fisher 344 (F344) rats and B6C3F1 mice. The F344 rat has a high incidence of testicular tumors and leukemias whereas the B6C3F1 mouse is associated with a high background of liver tumors (Table 8-23).

In the chronic bioassay, two or three dose levels of a test chemical and a vehicle control are administered to 50 males and 50 females (mice and rats), beginning at eight weeks of age, continuing throughout their lifespan. The route of administration can be via oral (gavage), dietary (mixed in feed), or inhalation (via inhalation chambers) exposure. Typically a number of short-term in vivo tests are conducted prior to the chronic bioassay to determine acute toxicity profiles, appropriate route of administration, and the maximum tolerated dose (MTD). Generally, the MTD is used to set the high dose in the chronic study. The use of the MTD as the upper dose level has been questioned by many investigators, as it is recognized that the doses selected represent those that are considered unrealistically high for human exposure. Pharmacokinetics and metabolism at high dose are frequently unrepresentative of those at lower doses; in addition, a general relationship between toxicity and carcinogenicity cannot be drawn for all classes of chemicals. During the study, food consumption and bodyweight gain should be monitored and the animals observed clinically on a regular basis;

Table 8-23

at necropsy, the tumor number, location, and diagnosis for each animal is thoroughly assessed.

Organ-Specific Bioassays and Multistage Animal Models

Many tissue-specific bioassays have been developed with the underlying goal being to produce a sensitive and reliable assay that could be conducted in a time frame shorter in duration than the two-year chronic bioassay. These assays are commonly used to detect carcinogenic activity of chemicals in various target organs (Weisburger and Williams, 1984). Of the many models available, three models, the liver, skin, and lung models are more widely used.

Carcinogenicity Testing in the Liver The liver represents a major target organ for chemical carcinogens. It has been estimated that nearly half of the chemicals tested in the two-year chronic bioassay by the NTP showed an increased incidence of liver cancer. The rodent liver has been used as an animal model for carcinogenesis since the 1930s. Early pioneering work by Peraino and Pitot as well as Farber showed the multistaged process that occurs in the liver. The multistage nature of carcinogenesis is paralleled in the animal models; the system is characterized by well-defined changes including the formation of initiated cells by genotoxic agents that then progress to preneoplastic focal lesions, which subsequently convert into neoplasms. The use of preneoplastic lesions as endpoints in carcinogenicity testing may shorten experiment from two years to a few months. Several rodent liver focus assays have been developed to assess the ability of a chemical to induce liver cancer and study the mechanisms involved in tumor development (Bannasch, 1986a,b; Williams, 1982). Liver carcinogenesis assays have been developed to study and distinguish chemicals that affect the initiation or promotion stage of hepatocarcinogenesis. During the assay for initiating activity of a chemical, the test substance is given prior to exposure to a promoting chemical. Although a single initiating dose can result in the induction of focal lesions, exposure over a several week period is often used to increase the sensitivity of the model (Parnell *et al.*, 1988; Williams, 1982). Phenobarbital is a commonly used tumor promoter; however, a wide range of chemicals have also been used as promoting agents (Solt and Farber, 1976; Oesterle and Deml, 1988). To assess the promoting activity of a chemical, the liver is initiated with a genotoxic chemical, often diethylnitrosamine. The test chemical is then administered for

a duration of weeks to several months, and chemicals with promoting activity may stimulate the proliferation of initiated cells or may inhibit the proliferation of the surrounding putatively normal cells. The dose of the initiating carcinogen should represent a dose that will not induce liver tumors during the course of the experiment.

Another method commonly used was developed in Japan by Ito and co-workers (Ogiso *et al.*, 1990; Shirai *et al.*, 1999; Ito *et al.*, 1994). The entire assay takes only eight weeks to perform. Rats are initiated with a single dose of diethylnitrosamine, followed by a two-week recovery period, after which point the animals are exposed to the test compound for eight weeks. After one week of exposure to the test substance, the animals are given a two-third partial hepatectomy. The control group receives the same initiation and partial hepatectomy, but is not exposed to the test chemical. Hepatic focal lesions, while individually are clonal in nature, express a number of phenotypic alterations in various enzyme markers. A common endpoint assessed is the formation of liver lesions that stain for GST-P, a marker that stains many focal lesions in the rat. Using this assay, these investigators demonstrated a significant correlation between the results obtained using this assay and medium- and long-term study results (Ogiso *et al.*, 1990). This group has also modified the original procedure to enable the detection of promoting agents. In this protocol, carcinogens are given over a four-week period to initiate the formation of focal lesion, after which, test chemicals are administered for an additional 24- to 36-week period (Ito *et al.*, 1996). In this manner, the ability of the test chemical to promote the growth of preneoplastic lesions can be assessed. The newborn mouse model originally described by Shubik and co-workers (Pietra *et al.*, 1959) has also been used as a model for hepatocarcinogenesis (Vesselinovitch *et al.*, 1978; Fujii, 1991). In this model, a single dose of diethylnitrosamine is administered to infant mice to initiate focal lesions. This step is then followed by exposure to test chemicals for several weeks to assess their potential to promote focal lesion development in the liver.

Identification of hepatic foci in H&E-stained sections is regarded as the most reliable approach for the diagnosis and quantification of preneoplastic liver lesions in rodents. Preneoplastic lesions are obligatory precursor lesions that can lead to liver tumors and will progress to benign and malignant liver cell tumors without further chemical exposure, and are used as endpoints in carcinogenicity testing (Ito *et al.*, 1989; Maronpot *et al.*, 1989; Pereira and Herren-Freund, 1988; Pitot *et al.*, 1987). In addition to the sensitive detection of these preneoplastic lesions in conventional H&E staining, a number of histochemically detectable phenotypic alterations have been used for their quantification; however, these markers are only useful in the rat model, as focal lesions in mice do not exhibit these same phenotypic markers.

Carcinogenicity Testing in the Skin The Mouse Skin model is one of the most extensively studied and used models for understanding multistage carcinogenesis. This model of carcinogenesis is an assay that has been used to dissect mechanisms of carcinogenesis and is also purported to be a useful intermediate-term cancer bioassay. The skin was the target organ of the first experimental induction of chemical carcinogenesis (Yamagiwa and Ichikawa, 1915). The early studies by Friedwald and Rous (1944) and Berenblub and Shubik (1947) introduced the two-stage concept of carcinogenesis in the skin (Fig. 8-31). This model exploits many of the unique properties of the mouse skin, one major being that the development of neoplasia can be followed visually. In addition, the number and relative size of papillomas and carcinomas can be quantified as the tumors progress.

Figure 8-31. Experiments demonstrating the initiation and promotion phases of carcinogenesis in mice. Group 2: application of promoter repeated at twice-weekly intervals for several months. Group 3: application of promoter delayed for several months and then applied twice weekly. Group 6: promoter applied at monthly intervals.

Both initiating and promoting activities of chemical carcinogens can be assessed using this model. In the promotion assay, a number of chemical carcinogens have been used to initiate cells in the mouse skin including urethane, UV light, benzo(a)pyrene, and dimethylbenzanthracene, with the latter of more common usage. The requirement for all initiating agents is to induce a genotoxic event that upon failure to repair DNA damage, results in the formation of a mutated cell. Grossly, initiated cells of the skin appear identical to normal skin. Initiation in skin is frequently linked with the mutation of the *CHr* gene. Because the terminally differentiated cells in the skin are no longer capable of undergoing cell division, only initiated cells retain their proliferative capacity and thus represent the cell populations that give rise to tumors. To assess promotion by a chemical, an initiating chemical is applied first and is followed by the administration of a test substance for several weeks on the shaved skin of mice (Slaga, 1984). The promotion of initiated keratinocytes is commonly assessed using the phorbol ester 12-*O*-tetradecanoylphorbol-13-acetate (TPA), which is routinely included as a positive control in this assay. The current hypothesis is that during the initiation stage the expansion or of initiated cells occurs as a result of inflammation and hyperplasia from either TPA or through mechanical wound healing mechanisms. Upon repeated application of tumor promoters, selective clonal expansion of initiated keratinocytes occurs, resulting in skin papillomas, which over time can progress to carcinomas. In the standard 2-stage protocol for mouse skin malignant progression is relatively rare with approximately 5% of the papillomas progressing to the carcinoma stage. For the detection of initiating activity, the test substance is applied to skin prior to promotion with phorbol esters. Several mouse models are available, including hairless mice, SENCAR mice, both of which have enhanced sensitivity to the induction of skin cancer (Brown and Balmain, 1995; Sundberg *et al.*, 1997).

Carcinogenicity Testing in the Lung Strain A mice are genetically susceptible to the development of lung tumors, with lung tumors being observed in control animals as early as three to four weeks of age with a steady increase to nearly 100% by 24 months of age (Shimkin and Stoner, 1975). Chemically induced tumors appear to be derived from hyperplastic lesions that progress to adenoma, carcinoma within adenoma, and ultimately, to carcinomas (Stoner *et al.*, 1993). In this model, carcinogenicity is typically assessed as an acceleration of tumor development rather

than an increase in tumor incidence. The protocol currently used is that the chemical is administered for a period of eight weeks, after which the animals remain on test for four additional months without chemical exposure. The strain A mouse lung tumor assay is sensitive to particular classes of chemicals, such as PAHs, nitrosamines, nitrosoureas, carbamates, aflatoxin, certain metals, and hydrazines (Maronpot *et al.*, 1986; Stoner, 1991; Stoner and Shimkin, 1985).

Carcinogenicity Testing in Other Organs Test systems to examine the ability of a chemical to promote neoplastic development at organ sites other than liver, skin, and lung have also been developed. The available systems include animal models directed at examining carcinogenicity in the kidney, bladder, pancreas, stomach, colon, small intestine, and oral cavity. These models vary in the initiating carcinogen used, and frequency, duration, and site of application, as well as duration of promoting chemical exposure. Table 8-24 provides an overview of the animal models available for these target organs.

Transgenic Animals in Carcinogenicity Assessment

Due to the development of animal models with genetic alterations that invoke a susceptibility to carcinogenesis by chemical agents, the use of transgenic and knockout animals in carcinogenicity assessment is gaining more popularity. The common models that have been used include the Tg.AC and rasH2 transgenic mice and p53^{-/-} and XPA^{-/-} knockout mice (Gulezian *et al.*, 2000). Recently, the feasibility of the use of these animal models as alternative assays for the two-year chronic bioassay was assessed in a collaborative between the Health and Environmental Sciences Institute (HESI) branch of the International Life Sciences Institute (ILSI). In this assessment, 21 chemicals were evaluated, encompassing genotoxic, nongenotoxic, and noncarcinogenic chemicals. The conclusions drawn from the scientific review suggested that these models appear to have usefulness as screening models for assessment of chemical carcinogenicity; however, they do not provide definitive proof of potential human carcinogenicity. Further the scientific panel suggested that these models could be used in place of the mouse two-year bioassay (Cohen *et al.*, 2001; Blaauboer *et al.*, 1998). Coupled with information on genotoxicity, particularly DNA reactivity, structure–activity relationships, results from other bioassays, and the results of other mechanistic investigations including toxicokinetics, metabolism, and mechanistic information, these alternate mouse models for carcinogenicity appear to be useful models for assessing the carcinogenicity of chemicals. In general, replacement of the two-year rodent bioassay by transgenic mouse assay have not been as successful as originally planned (Boverhof, 2011). However, as models for studying the roles of specific pathways and mechanisms in the carcinogenesis process, these models remain an excellent resource.

New Approaches A major concern for the correct evaluation of the safety of chemicals, and as mixtures is the need to obtain reliable and pertinent scientific information on which to develop proper risk evaluation and assessment. Our current bioassays approaches have been criticized as being too time consuming and not pertinent to human health. Research during the last decade of the 20th century and the turn of the 21st century have resulted in a dramatic increase in our knowledge of the cellular and molecular pathways that contribute to the induction and prevention of cancer. This coupled with technological advances in high-throughput

Table 8-24

Target Organ Models for Studying Chemically Induced Carcinogenesis

ORGAN	SPECIES	INITIATING CARCINOGEN	INITIATOR DURATION	CARCINOGEN (PROMOTER) DURATION	REFERENCES

assays, and computational science has raised the question if the current approaches for carcinogenesis evaluation of chemicals (and mixtures) should be reevaluated. Following a NRC report in 2007 (Toxicity Testing in the 21st Century: A Vision and a Strategy), several approaches have begun utilizing high-throughput and computational approaches to evaluating the effects of chemicals on biological processes and pathways that are important in toxicity (including cancer). These approaches are directed to using cells, cell lines and components of cells. Two approaches currently well underway include the USEPA Toxcast program and the NTP/NIEHS lead Tox 21 program (tox21 is a consortium of NIH, FDA, USEPA) utilizing this approach.

CHEMICAL CARCINOGENESIS IN HUMANS

Recently, the IARC (Vol 100) has reported a review of chemically induced cancer in humans. This body has identified and classified 103 compounds as carcinogenic in humans. This review is divided into four major categories of carcinogens deemed to be human carcinogens by the IARC. These include pharmaceuticals, metals, biologicals, and radiation. A number of factors have been implicated in the induction of cancer in humans. Infectious agents, lifestyle, medical treatments, environmental, and occupational exposure account either directly or indirectly to the majority of cancers seen

in humans. Of these, the component that contributes the most to human cancer induction and progression is lifestyle: tobacco use, alcohol use, and poor diet (Table 8-25). Tobacco usage either through smoking tobacco, chewing tobacco, or tobacco snuff-type products is estimated to be responsible for 25% to 40% of all human cancers. In particular, a strong correlation between tobacco usage and mouth, larynx, lung, esophageal, and bladder cancer exists. It has been estimated (Doll and Peto, 1981) that 85% to 90% of all lung cancer cases in the United States are a direct result of tobacco

Table 8-25

Carcinogenic Factors Associated With Lifestyle

CHEMICAL(S)	NEOPLASM(S)
Alcohol beverage	Esophagus, liver, oropharynx, and larynx
Aflatoxins	Liver
Betel chewing	Mouth
Dietary intake (fat, protein, calories)	Breast, colon, endometrium, gallbladder
Tobacco smoking	Mouth, pharynx, larynx, lung, esophagus, bladder

Table 8-26

Occupational Human Carcinogens

AGENT	INDUSTRIAL PROCESS	NEOPLASMS
Asbestos	Construction, asbestos mining	Peritoneum, bronchus
Arsenic	Mining and smelting	Skin, bronchus, liver
Alkylating agents (mechloroethamine hydrochloride and bis[chloromethyl]ether)	Chemical manufacturing	Bronchus
Benzene	Chemical manufacturing	Bone marrow
Benzidine, β -naphthylamine	Dye and textile	Urinary bladder
Chromium and chromates	Tanning, pigment making	Nasal sinus, bronchus
Nickel	Nickel refining	Nasal sinus, bronchus
Polynuclear aromatic hydrocarbons	Steel making, roofing, chimney cleaning	Skin, scrotum, bronchus
Vinyl chloride monomer	Chemical manufacturing	Liver
Wood dust	Cabinet making	Nasal sinus
Beryllium	Aircraft manufacturing, electronics	Bronchus
Cadmium	Smelting	Bronchus
Ethylene oxide	Production of hospital supplies	Bone marrow
Formaldehyde	Plastic, textile, and chemical	Nasal sinus, bronchus
Polychlorinated biphenyls	Electrical-equipment production and maintenance	Liver

use. The induction of pancreatic cancer also appears to have a linkage to tobacco use. Alcohol consumption also contribute anywhere from 2% to 4% of cancers of the esophagus, liver, and larynx.

Poor diets whether high-fat, low-protein, high-calories or diets lacking in needed antioxidants and minerals account for anywhere from 10% to 70% of human cancers. Diet contaminated by molds such as *Aspergillus flavus* (which produces aflatoxin B1) have been linked epidemiologically to a higher incidence of liver cancer. It also appears that aflatoxin B1 exposure coupled with hepatitis B virus infection produces an increased incidence of liver cancer compared to aflatoxin B1 or hepatitis B exposure individually. Mold-contaminated foodstuffs have also been shown to produce nitroso compounds.

There is substantial evidence that overnutrition either through excess calories and/or high-fat diets contribute to a number of human cancers (Doll and Peto, 1981). In particular, high-fat and high-calorie diets have been linked to breast, colon, and gall bladder cancer in humans. Diets poor in antioxidants and/or vitamins such as vitamin A and vitamin E probably also contribute to the onset of cancer. The method of cooking may also influence the production of carcinogens produced in the cooking process. Carcinogenic HCAs and PAHs are formed during broiling and grilling of meat. Acrylamide, a suspected human carcinogen, has been found in fried foods at low concentrations.

A number of occupations have been associated with the development of specific cancers (Table 8-26). As noted earlier, the linkage between chimney sweeps who as young boys in England were exposed to PAHs through the constant exposure to soot developed scrotal cancer. The linkage between occupational exposure to asbestos and the development of bronchiogenic carcinoma and as well as malignant mesothelioma has been clearly established. The appearance of bronchiogenic carcinoma was much higher in shipyard workers who were exposed to both asbestos and cigarette

smoking. Muscat and Wynder (1995) noted no association between cigarette smoking and mesothelioma formation. Similarly, asbestos exposure by itself (without smoking) does not seem to increase the risk of bronchiogenic carcinoma. Aromatic amines used in the chemical and dye industries have been shown to produce or induce bladder cancer in humans. Prolonged high exposure to benzene in an occupational setting has been linked to the formation of acute myelogenous leukemia in humans.

A number of drugs and medical diagnostic tools have also been linked to the induction of human cancer (Table 8-27). Anticancer drugs such as the alkylating agent cyclophosphamide have been

Table 8-27

Human Carcinogenic Chemicals Associated With Medical Therapy and Diagnosis

CHEMICAL OR DRUG	ASSOCIATED NEOPLASMS
Alkylating agents (cyclophosphamide, melphalan)	Bladder, leukemia
Azathioprine	Lymphoma, reticulum cell sarcoma, skin, Kaposi sarcoma
Chloramphenicol	Leukemia
Diethylstilbestrol	Vagina (clear cell carcinoma)
Estrogens	Liver cell adenoma, endometrium, skin
Phenacetin	Renal pelvis (carcinoma)
Phenytoin	Lymphoma, neuroblastoma
Thorotrast	Liver (angiosarcoma)

associated with bladder tumors and leukemia in patients receiving these treatments. The administration of the synthetic estrogenic compound diethylstilbestrol to pregnant women in order to improve embryo implantation and prevent spontaneous abortion has been shown to result in the formation of clear cell carcinomas of the vagina in the female offspring of mothers treated with diethylstilbestrol during pregnancy. The use of oral contraceptives containing synthetic estrogens as their major or only component has been implicated in the induction of liver cell adenomas. In addition, an association exists between prolonged use of estrogenic oral contraceptives and an increase incidence of premenopausal breast cancer. Androgenic steroids and synthetic testosterone compounds have been implicated in hepatocellular carcinoma induction. Therapeutic immunosuppression given to transplant patients or arising secondary to selective diseases such as AIDS result in an increase in a variety of different neoplasms. These results further support the role of the immune system in identifying and removing early preneoplastic cells from the body. In addition, the previously used diagnostic tracer Thorotrast has been sufficiently linked to the formation of hemangiosarcomas.

CLASSIFICATION EVALUATION OF CARCINOGENICITY IN HUMANS

The assessment and designation of a chemical agent or a mixture of chemicals as carcinogenic in humans is evaluated by various agencies worldwide. The evaluation usually encompasses epidemiological, experimental animal, and in vitro data utilizing assays as described earlier in this chapter. One of the first schemes for the classification of an agent's carcinogenicity was devised by the IARC (Table 8-28). The IARC approach assigns the chemical or mixture to one of five groupings based upon strength of evidence for the agent's possible, probable, or definite carcinogenicity to humans. In Group one classification, the agent or mixture is classified as definitely carcinogenic to humans. The second grouping is Group 2A in which the agent is probably carcinogenic to humans. In Group 2B, the agent is classified as possibly carcinogenic to humans. Group 3, the agent is not classifiable. And in the last group, Group 4, the agent is not carcinogenic to humans. The IARC produces a series of monographs that describe the methodology for the evaluation of specific chemicals and the rationale for their final classification.

Table 8-28

IARC Classification of the Evaluation of Carcinogenicity for Human Beings

GROUP	EVIDENCE
1. Agent is carcinogenic to humans	Human data strong Animal data strong
2A. Agent is probably carcinogenic to humans	Human epidemiology data suggestive Animal data positive
2B. Agent is possibly carcinogenic to humans	Human epidemiology data weak Animal data positive
3. Agent is not classifiable as to carcinogenicity to humans	Human and animal data inadequate
4. Agent is probably not carcinogenic to humans	Human and animal data negative

Table 8-29

USEPA Cancer Guidelines Descriptors

Carcinogenic to humans:

- strong evidence of human carcinogenicity, including convincing epidemiological evidence of a causal association between human exposure and cancer
- the mode(s) of carcinogenic action and associated key precursor events have been identified in animals, and there is strong evidence that the key precursor events in animals are anticipated to occur in humans

Likely to be carcinogenic to humans:

- weight of the evidence is adequate to demonstrate carcinogenic potential to an agent in animal experiments in more than one species, sex, strain, site, or exposure route, with or without evidence of carcinogenicity in humans

Suggestive evidence of carcinogenic potential:

- the weight of evidence is suggestive of carcinogenicity; a concern for potential carcinogenic effects in humans is raised, but the data are judged not sufficient for a stronger conclusion

Inadequate information to assess carcinogenic potential:

- available data are judged inadequate for applying one of the other descriptors

Not likely to be carcinogenic to humans:

- this descriptor is appropriate when the available data are considered robust, there is no basis for human hazard concern, evidence in both humans and animals that the agent is not carcinogenic

Currently, 100 chemical agents or mixtures or exposure circumstances have been classified by IARC as falling in Group 1, which shows sufficient evidence for carcinogenicity to humans.

Similar classifications exist for the USEPA, the Food & Drug Administration, and the European Community (EC). The classification of agents with regard to human carcinogenicity can many times be very difficult in particular, when animal data and/or epidemiological data in humans are inconclusive or confounded.

New USEPA Guidelines for Cancer Risk Assessment (2005) uses descriptors for defining the relative carcinogenic risk to humans (Table 8-29). These descriptors include carcinogenic to humans, likely to be carcinogenic to humans, suggestive evidence of carcinogenic potential, inadequate information to access carcinogenic potential, and, not likely to be carcinogenic in humans. The EPA Guidelines take into account the understanding of the mode of carcinogenic action and associated key precursor events needed for the cancer to form (Table 8-30). Central to the USEPA Guidelines for Cancer Risk Assessment is the utilization of the mode of action framework to define the key events in rodents and assessment of

Table 8-30

USEPA Mode of Action Definitions

Mode of action: Key events and processes, starting with the interaction of an agent with a cell, through functional and anatomical changes, resulting in cancer or other health endpoints

Key event: Empirically observable precursor step that is itself a necessary element of the mode of action or is a biologically based marker for such an element

Table 8-31

USEPA Mode of Action Framework

Mode of action criteria

Summary description of the hypothesized mode of action
 Identification of key events
 Strength, consistency, specificity of association
 Dose–response concordance
 Temporal relationship
 Biological plausibility and coherence
 Consideration of the possibility of other MOAs
 Is the mode of action sufficiently supported in the test animals?
 Is the mode of action relevant to humans?
 Which populations or life stages can be particularly susceptible to the mode of action?

whether those same key events and mode of action can occur in humans (Table 8-31). This approach is similar to that has been developed by the International Program on Chemical Safety and by panels in the International Life Sciences Institute.

The current listing of chemical, occupations, or behaviors deemed to be carcinogenic in humans by IARC and the NTP are noted in Tables 8-32 to 8-33, respectively.

SUMMARY

The induction of cancer by chemicals is well established in animal models as well as in humans. Linkages between chemicals found in human lifestyle, occupational exposure, and environmental exposure provides strong evidence for the induction or contribution to environmental occupational lifestyle carcinogens to human cancer. Cancer is a multistage process in its most reductive form involves initial mutational events followed by changes in gene expression leading to the selected clonal proliferation of the precancerous cell. Neoplasia appears to exhibit multiple characteristics including increase selective lesion growth (through sustained cell proliferation and /or resistance to apoptosis), the induction of angiogenesis, enabling replicative immortality, activation of factors that influence invasion and metastasis, evasion of normal growth suppression, modulation of energy metabolism, and the avoidance of attack by the immune system. The

Table 8-32

Known Human Carcinogens: International Agency for Research on Cancer

Acetaldehyde	Estrogen–progestogen therapy	Painter (workplace exposure)
Acid mists, strong inorganic	Estrogen–progestogen oral contraceptives (combined)	3,4,5,3',4'-Pentachlorobiphenyl (PCB-126)
Aflatoxins	Ethanol in alcoholic beverages	2,3,4,7,8-Pentachlorodibenzofuran
Alcoholic beverages	Ethylene oxide	Phenacetin (and mixtures containing it)
Aluminum production	Etoposide	Phosphorus-32, as phosphate
4-Aminobiphenyl	Etoposide in combination with cisplatin and bleomycin	Plutonium
Areca nut	Fission products, including strontium-90	Radioiodines, including iodine-131
Aristolochic acid	Formaldehyde	Radionuclides, α -particle-emitting
Arsenic and inorganic arsenic compounds	Haematite mining	Radionuclides, β -particle-emitting,
Asbestos (all forms)	<i>Helicobacter pylori</i>	Radium-224 and its decay products
Auramine production	Hepatitis B virus	Radium-226 and its decay products
Azathioprine	Hepatitis C virus	Radium-228 and its decay products
Benzene	Human immunodeficiency virus type 1	Radon-222 and its decay products
Benzidine and dyes metabolized to benzidine	Human papilloma virus (HPV)	Rubber manufacturing industry
Benzo[<i>a</i>]pyrene	Human T-cell lymphotropic virus type I	Salted fish (Chinese-style)
Beryllium and beryllium compounds	Ionizing radiation	Schistosoma haematobium (flatworm)
Betel quid, with or without tobacco	Iron and steel founding	Semustine (methyl-CCNU)
Bis(chloromethyl)ether and chloromethyl methyl ether	Isopropyl alcohol	Shale oils
Busulfan	Kaposi sarcoma herpesvirus	Silica dust, crystalline (cristobalite)
1,3-Butadiene	Leather dust	Solar radiation
Cadmium and cadmium compounds	Magenta production	Soot (exposure of chimney sweeps)
Chlorambucil	Melphalan	Sulfur mustard
Chlornaphazine	Methoxsalen (8-methoxy psoralen) plus ultraviolet A radiation	Tamoxifen
Chromium (VI) compounds	4,4'-Methylenebis(chloroaniline) (MOCA)	2,3,7,8-Tetrachlorodibenzo-para-dioxin
Clonorchis sinensis (infection with)	Mineral oils, untreated or mildly treated	Thiotepa
Coal, household combustion	MOPP	Thorium-232 and its decay products
Coal gasification	2-Naphthylamine	Tobacco, smokeless
Coal tar distillation	Neutron radiation	Tobacco smoke, secondhand
Coal tar pitch	Nickel compounds	Tobacco smoking
Coke production	<i>N</i> '-Nitrosornicotine (NNN) and 4-(<i>N</i> -Nitrosomethylamino)-1-(3-pyridyl)-1-butanone (NNK)	ortho-Toluidine
Cyclophosphamide	Opisthorchis viverrini (liver fluke)	Treosulfan
Cyclosporine		Ultraviolet (UV) including UVA, UVB, and UVC
Diethylstilbestrol		Ultraviolet-emitting tanning devices
Epstein–Barr virus (infection with)		Vinyl chloride
Erionite		Wood dust
Estrogen postmenopausal therapy		X- and γ -radiation

Table 8-33

Known to Be Human Carcinogens National Toxicology Program 12th Report on Carcinogens

Aflatoxins	Diethylstilbestrol (DES)	Tamoxifen
Alcoholic beverage consumption	Dyes metabolized to benzidine	TCDD; "dioxin"
4-Aminobiphenyl	Environmental tobacco smoke	Thiotepa
Analgesic mixtures containing phenacetin	Erionite	Thorium dioxide
Aristolochic acids	Estrogens, steroidal	Tobacco smoking
Arsenic compounds, inorganic	Ethylene oxide	Vinyl chloride
Asbestos	Formaldehyde	Ultraviolet radiation, broad spectrum
Azathioprine	Hepatitis B virus	UV radiation
Benzene	Hepatitis C virus	Wood dust
Benzidine	Human papilloma viruses: some genital-mucosal types	X-radiation and γ -radiation
Beryllium and beryllium compounds	Melphalan	
1,3-Butadiene	Methoxsalen with ultraviolet A therapy (PUVA)	
1,4-Butanediol dimethylsulfonate (busulfan, Myleran)	Mineral oils (untreated and mildly treated)	
Cadmium and cadmium compounds	Mustard gas	
Chlorambucil	2-Naphthylamine	
1-(2-Chloroethyl)-3-(4-methylcyclohexyl)-1-nitrosourea (MeCCNU)	Neutrons	
bis(chloromethyl) ether and technical-grade chloromethyl methyl ether	Nickel compounds	
Chromium hexavalent compounds	Oral tobacco products	
Coal tar pitches	Radon	
Coal tars	Silica, crystalline (respirable size)	
Coke oven emissions	Solar radiation	
Cyclophosphamide	Soots	
Cyclosporin A	Strong inorganic acid mists containing sulfuric acid	
	Sunlamps or sun beds, exposure to	

multistage nature and characteristics of the process have been extensively examined with regard to molecular, cellular, tissue, and organ events.

WHAT IS GENETIC TOXICOLOGY?

Genetic toxicology is a branch of the field of toxicology that assesses the effects of chemical and physical agents on the hereditary material (DNA) and on the genetic processes of living cells. Such effects can be assessed directly by measuring the interaction of agents with DNA or more indirectly through the assessment of DNA repair or the production of gene mutations or chromosome alterations. Given the risk assessment framework of this chapter, it is important at the outset to distinguish between genotoxicity and mutagenicity. Genotoxicity covers a broader spectrum of endpoints than mutagenicity. For example, unscheduled DNA synthesis (UDS), sister chromatid exchanges (SCEs), and DNA strand breaks are measures of genotoxicity, not mutagenicity because they are not themselves transmissible from cell to cell or generation to generation. Mutagenicity on the other hand refers to the production of transmissible genetic alterations. In the last few years, there has been an increased emphasis on the role of epigenetic changes in the production of altered phenotypes. Such changes can be transmitted and so it is appropriate to include epigenetic changes such as alterations in DNA methylation or in histones involved in the

control of gene expression as genotoxic endpoints. However, they are not mutations by definition because they do not involve changes in DNA sequence (Hamilton, 2011).

This chapter discusses the history of the development of the field of genetic toxicology, the use of genetic toxicology data in cancer and genetic risk assessments, the mechanisms underlying genetic toxicology assays, the assays that can be used for detecting genotoxic endpoints, the use of the same assays for better understanding mechanisms of mutagenesis, and new methods for the assessment of genetic alterations. The field is evolving rapidly, and a review of its past and present state will set the stage to allow for a consideration of what are likely next major landmarks.

HISTORY OF GENETIC TOXICOLOGY

The field of genetic toxicology can be considered to have its roots in the pioneering work of H.J. Muller (1927), who showed that x-rays could induce mutations in the fruit fly, *Drosophila*. In his studies he showed not only that radiation exposure could increase the overall frequencies of mutations but also that the types of mutations induced were exactly the same in effect, or phenotype, as those

observed in the absence of radiation exposure. Thus, the induced mutagenic responses should be assessed in relation to background mutations. As a conclusion to this study of radiation-induced mutations, Muller predicted the utility of mutagenesis studies not only for the study of mutations themselves but also for gene mapping approaches.

Karl Sax (1938) built upon Muller's original studies of radiation-induced mutations by showing that X-rays could also induce structural alterations to chromosomes in *Tradescantia* pollen grains. Sax and his colleagues, notably in the absence of knowledge of DNA structure and chromosomal organization, showed that at least two critical lesions in a nuclear target are required for the production of an exchange within (intrachromosome) or between (interchromosome) chromosomes. We know now that the lesions identified by Sax are DNA double-strand breaks, base damages, or multiply damaged sites (reviewed by Ward, 1988). In addition, Sax and colleagues (Sax, 1939; Sax and Luippold, 1952) showed that the yield of chromosome aberrations was reduced if the total dose of x-rays was delivered over extended periods of time or split into two fractions separated by several hours. These observations led to the concept of restitution of radiation-induced damage, which was later recognized as involving specific DNA repair processes (see below).

Consideration of the genetic effects of exogenous agents on cells was expanded to include chemicals in 1946, when Charlotte Auerbach and colleagues reported that mustard gas could induce mutations in *Drosophila* and that these mutations were phenotypically similar to those induced by x-rays (Auerbach and Robson, 1946). Thus, the field of chemical mutagenesis was initiated to run in parallel with studies of radiation mutagenesis. These original studies of Auerbach (actually conducted in 1941) are placed in a historical and biological perspective by the delightful review of Geoffrey Beale (1993).

Although the scientific value of the analysis of mutations in *Drosophila* was clear, there was an impression that the extrapolation to predict similar effects in human populations was too wide a step. Thus, a research effort of great magnitude was initiated to attempt to assess radiation-induced mutations in mice. This effort resulted in the publication by William Russell (1951) of data on x-ray-induced mutations using a mouse-specific-locus mutation assay. These data clearly showed that the type of results obtained with *Drosophila* could be replicated in a mammalian system. The mouse tester strain developed for the specific-locus assay has recessive mutations at seven loci coding for visible mutations, such as coat color, eye color, and ear shape. This homozygous recessive tester strain can be used for identifying recessive mutations induced in wild type genes at the same loci in mice treated with radiation or chemical mutagens. It was noteworthy that the mutation rate for x-ray-induced mutations in germ cells was similar in mouse and *Drosophila*. Subsequent studies by Liane Russell and colleagues showed that chemicals could induce mutations at the same seven loci (Russell *et al.*, 1981).

Over the next 20 years, genetic toxicologists investigated the induction of mutations and chromosomal alterations in somatic and germ cells, largely following exposures to radiation, but increasingly using chemical mutagens as well. The ability to grow cells in vitro, either as primary cultures or as transformed cell lines, enhanced these quantitative studies. The in vitro culture of human lymphocytes, stimulated to reenter the cell cycle by phytohemagglutinin, greatly expanded the information on the assessment of chromosomal alterations in human cells (an excellent review by Hsu [1979] is recommended). It also became feasible to use cytogenetic alterations in human lymphocytes as a biodosimeter for assessing human exposures to ionizing radiations (Bender and Gooch, 1962).

Two events during the 1970s served to expand the utility of mutagenicity data into the realm of risk assessment. The Millers and their colleagues (Miller and Miller, 1977) showed that chemical carcinogens could react to form stable, covalent derivatives with DNA, RNA, and proteins both in vitro and in vivo. In addition, they reported that these derivatives could require the metabolism of the parent chemical to form reactive metabolites. This metabolism is required for some chemicals to become mutagens and carcinogens. Metabolic capability is endogenous in vivo, but most cell lines in vitro do not express this capacity. To overcome this for in vitro mutagenicity studies, Heinrich Malling and colleagues developed an exogenous metabolizing system based on a rodent liver homogenate (S9) (Malling and Frantz, 1973; Malling, 2004). Although this exogenous metabolism system has had utility, it does have drawbacks related to species and tissue specificity and loss of cellular compartmentalization. The development of transgenic cell lines containing P450 genes has overcome this drawback to some extent (Sawada and Kamataki, 1998; Crespi and Miller, 1999).

The second development in the 1970s that changed the field of genetic toxicology was the development by Bruce Ames *et al.* (1975) of a simple, inexpensive mutation assay with the bacterium *Salmonella typhimurium*. This assay can be used to detect chemically induced reverse mutations in several histidine genes and can include the exogenous metabolizing S9 system described above. The Ames assay, as it is generally called, has been expanded and modified to enhance its performance as discussed below (under section "Gene Mutations in Prokaryotes"). The assay has been used extensively, especially for hazard identification, as part of the cancer risk assessment process. This use was based on the assumption that carcinogens were mutagens and that cancer required mutation induction. This latter dogma proved to be somewhat inhibitory to the field of genetic toxicology because it provided a framework that was too rigid. Nonetheless, over the decade of the mid-1970s to mid-1980s somewhere on the order of 200 short-term genotoxicity and mutagenicity assays were developed for screening potentially carcinogenic chemicals. The screens included mutation induction, DNA damage, DNA repair, and cell killing or other genotoxic activities.

Several international collaborative studies were organized to establish the sensitivity and specificity of a select group of assays as well as to assess interlaboratory variation (International Program on Chemical Safety [IPCS], 1988). Most assays were able to detect carcinogens or noncarcinogens with an efficiency of about 70% as compared with the outcome of two-year cancer bioassays. There are a number of possible reasons for the imperfect correspondence, the most likely being that there is a group of chemical carcinogens that do not induce cancer by a direct mutagenic action. The latter point was addressed to some extent by Tennant *et al.* (1987), who compared the effectiveness of a small standard battery of well-characterized short-term assays to identify carcinogens. Again, this battery predicted about 70% of known carcinogens. Subsequently, the lack of a tight correlation between carcinogenicity and mutagenicity (and the converse, noncarcinogenicity and nonmutagenicity) was found to be due to the fact that some chemicals were not directly mutagenic but instead induced the damage necessary for tumor development indirectly by, for example, clonally expanding preexisting mutant cells (ie, tumor promotion) or through the production of reactive oxygen species. Such chemicals were given the rather unfortunate name of *nongenotoxic* to contrast them with genotoxic ones; the classification as *not directly mutagenic* is more appropriate. In the context of the mechanism of their mutagenicity, it is preferable to distinguish between DNA-reactivity and its correlate non-DNA-reactivity. Emphasis has recently been placed on

identifying mechanisms whereby nondirectly mutagenic chemicals can be involved in tumor production. Those identified include cytotoxicity with regenerative cell proliferation, mitogenicity, receptor-mediated processes, changes in methylation status, and alterations in cell–cell communication.

In the last 10 years or so, the field of genetic toxicology has moved away from the short-term assay approach for assessing carcinogenicity to a much more mechanistic approach, fueled to quite an extent by the advances in molecular biology. The ability to manipulate and characterize DNA, RNA, and proteins and to understand basic cellular processes and how they can be perturbed has advanced enormously over this period. Knowing how to take advantage of these technical developments is paramount. This chapter addresses these changes in approach to genetic toxicology: the assays for qualitative and quantitative assessment of cellular changes induced by chemical and physical agents, the underlying molecular mechanisms for these changes, and how such information can be incorporated into cancer and genetic risk assessments. In addition, the way forward for the field is addressed in the form of an epilogue. Thus, the preceding historical overview sets the stage for the rest of the chapter.

HEALTH IMPACT OF GENETIC ALTERATIONS

The importance of mutations and chromosomal alterations for human health is evident from their roles in genetic disorders, including birth defects and cancer. Therefore, mutations in both germ cells and somatic cells need to be considered when an overall risk resulting from mutations is concerned.

Somatic Cells

An association between mutation and cancer has long been evident, such as through the correlation between the mutagenicity and carcinogenicity of chemicals, especially in biological systems that have the requisite metabolic activation capabilities. Moreover, human chromosome instability syndromes and DNA repair deficiencies are associated with increased cancer risk (Friedberg, 1985). Cancer cytogenetics has greatly strengthened the association in that specific chromosomal alterations, including deletions, translocations, inversions, and amplifications, have been implicated in many human leukemias and lymphomas as well as in some solid tumors (Rabbitts, 1994; Zhang *et al.*, 2010).

Critical evidence that mutation plays a central role in cancer has come from molecular studies of oncogenes and tumor-suppressor genes. Oncogenes are genes that stimulate the transformation of normal cells into cancer cells (Bishop, 1991). They originate when genes called proto-oncogenes, involved in normal cellular growth and development, are genetically altered. Normal regulation of cellular proliferation requires a balance between factors that promote growth and those that restrict it. Mutational alteration of proto-oncogenes can lead to overexpression of their growth-stimulating activity, whereas mutations that inactivate tumor-suppressor genes, which normally restrain cellular proliferation, free cells from their inhibitory influence (Hanahan and Weinberg, 2000, 2011).

The action of oncogenes is genetically dominant in that a single active oncogene is expressed, even though its normal allele is present in the same cell. Proto-oncogenes can be converted into active oncogenes by point mutations or chromosomal alterations. Base pair substitutions in *ras* proto-oncogenes are found in many human tumors (Bishop, 1991; Barrett, 1993; Croce, 2008). Among chromosomal alterations that activate proto-oncogenes,

translocations are especially prevalent (Rabbitts, 1994; Croce, 2008; Zhang *et al.*, 2010). For example, Burkitt lymphoma involves a translocation between the long arm of chromosome eight, which is the site of the *c-MYC* oncogene, and chromosome 14 (about 90% of cases), 22, or 2. A translocation can activate a proto-oncogene by moving it to a new chromosomal location, typically the site of a T-cell receptor or immunoglobulin gene, where its expression is enhanced. A similar translocation-based mechanism also applies to various other hematopoietic cancers. Alternatively, the translocation may join two genes, resulting in a protein fusion that contributes to cancer development. Fusions have been implicated in other hematopoietic cancers and some solid tumors (Rabbitts, 1994; Croce, 2008; Zhang *et al.*, 2010). Like translocations, other chromosomal alterations can activate proto-oncogenes, and genetic amplification of oncogenes can magnify their expression (Bishop, 1991; Croce, 2008).

Mutational inactivation or deletion of tumor-suppressor genes has been implicated in many cancers. Unlike oncogenes, the cancer-causing alleles that arise from tumor-suppressor genes are typically recessive in that they are not expressed when they are heterozygous (Evans and Prosser, 1992). However, several genetic mechanisms, including mutation, deletion, chromosome loss, and mitotic recombination, can cause loss of heterozygosity (LOH), in which the normal dominant allele is inactivated or eliminated. LOH leads to the expression of the recessive cancer gene in a formerly heterozygous cell (Cavenee *et al.*, 1983; Turner *et al.*, 2003; Reliene *et al.*, 2007). The inactivation of tumor-suppressor genes has been associated with various cancers, including those of the eye, kidney, colon, brain, breast, lung, and bladder (Fearon and Vogelstein, 1990; Marshall, 1991). Gene mutations in a tumor-suppressor gene called *P53*, located on chromosome 17, occur in many different human cancers, and molecular characterization of *P53* mutations has linked specific human cancers to mutagen exposures (Harris, 1993; Aguilar *et al.*, 1994; Royds and Iacopetta, 2006).

In the simplest model for the action of tumor-suppressor genes, two events are considered to be required for the development of retinoblastoma, a tumor of the eye, because both normal alleles must be inactivated or lost (Knudson, 1997). In sporadic forms of the cancer (ie, no family history), the two genetic events occur independently, but in familial forms (eg, familial retinoblastoma), the first mutation is inherited, leaving the need for only a single additional event for expression. The strong predisposition to cancer in the inherited disease stems from the high likelihood that a LOH will occur by mutation, recombination, or aneuploidy in at least one or a few cells in the development of the affected organ. The simple model involving two events and a single pair of alleles cannot explain all observations concerning tumor-suppressor genes because many cancers involve more than one tumor-suppressor gene. For example, the childhood kidney tumor called Wilms tumor can be caused by damage in at least three different genes (Marshall, 1991), and colorectal carcinomas are often found to have lost not only the wild-type *P53* tumor-suppressor gene but also other tumor-suppressor genes (Fearon and Vogelstein, 1990; Stoler *et al.*, 1999). Moreover, a single mutation in a tumor-suppressor gene, even though not fully expressed, may contribute to carcinogenesis. For example, a single *P53* mutation in a developing colorectal tumor may confer a growth advantage that contributes to the development of the disease (Venkatchalam *et al.*, 1998). Subsequent LOH will increase the growth advantage as the tumor progresses from benign to malignant (Fearon and Vogelstein, 1990). In this regard (mutation and selection), carcinogenesis has been likened to an evolutionary process, with genomic instability providing the substrate and with growth advantage as the selection pressure (Gatenby and Vincent, 2003; Fischer *et al.*, 2004).

Many cancers involve both activation of oncogenes and inactivation of tumor-suppressor genes (Fearon and Vogelstein, 1990; Bishop, 1991; Croce, 2008). The observation of multiple genetic changes supports the view that cancer results from an accumulation of genetic alterations and that carcinogenesis is a multistep process (Kinzler and Vogelstein, 1996; Hahn *et al.*, 1999; Stoler *et al.*, 1999; Croce, 2008). At least three stages have been defined in carcinogenesis: initiation, promotion, and progression (Barrett, 1993). *Initiation* involves the induction of a genetic alteration, such as the mutational activation of a *ras* proto-oncogene by a mutagen. It is an irreversible step that starts the process toward cancer. *Promotion* involves cellular proliferation in an initiated cell population. Promotion can lead to the development of benign tumors such as papillomas. Agents called promoters stimulate this process. Promoters may be mutagenic but are not necessarily so. *Progression* involves the continuation of cell proliferation and the accumulation of additional irreversible genetic changes; it is marked by increasing genetic instability and malignancy. More recent studies are beginning to change this view, leading to the concept of acquired capabilities (Hanahan and Weinberg, 2000). In their *Hallmarks of Cancer*, Hanahan and Weinberg (2000) describe a set of six acquired characteristics that are essential for the formation of all tumors irrespective of tumor type and species. These characteristics are broadly described as follows: self-sufficiency in growth signals, insensitivity to antigrowth signals, evading apoptosis, limitless replicative potential, sustained angiogenesis, and tissue invasion and metastasis. It seems probable that there is no specific order for obtaining these characteristics. Hanahan and Weinberg have revisited their hallmarks concept, and, based on progress in the field over the past decade, they have added two emerging hallmarks of potential generality to their existing six (Hanahan and Weinberg, 2011). These are reprogramming of energy metabolism and evading immune destruction. In addition, they describe genome instability and inflammation as general features that underlie their now eight hallmarks (Hanahan and Weinberg, 2011).

Genomic instability is a feature of all cancers, with the great majority having a large number of chromosomal and gene mutations and aneuploidies. In fact, one of the difficulties in trying to unravel the mechanisms of formation of tumors is establishing which genetic alterations are informative and which are merely incidental and a product of the cancer process itself. The advent of ultrahigh throughput sequencing has allowed for the complete sequencing and subsequent characterization of genomic changes in a number of tumor types. The outcome has been an ability to classify the genomic changes as drivers and passengers, with the former being essential key events in tumor formation, and the latter basically “coming along for the ride” (Stratton *et al.*, 2009; Pleasance *et al.*, 2010).

Gene mutations, chromosome aberrations, and aneuploidy are all implicated in the development of cancer. Mutagens and clastogens (chromosome breaking agents) contribute to carcinogenesis as initiators. Their role does not have to be restricted to initiation, however, in that mutagens, clastogens and aneugens (agents that induce aneuploidy) may contribute to the multiple genetic alterations that characterize progression or the development of acquired capabilities. Other agents that contribute to carcinogenesis, such as promoters, need not be mutagens. However, the role of mutations is critical, and analyzing mutations and mutagenic effects is essential for understanding and predicting chemical carcinogenesis.

Germ Cells

The relevance of gene mutations to health is evident from the many disorders that are inherited as simple Mendelian characteristics

(Mohrenweiser, 1991). About 1.3% of newborns suffer from autosomal dominant (1%), autosomal recessive (0.25%), or sex-linked (0.05%) genetic diseases (National Research Council [NRC], 2007a,b; Sankaranarayanan, 1998; Elespuru and Sankaranarayanan, 2007). Molecular analysis of the mutations responsible for Mendelian diseases has revealed that almost half of these mutations are base pair substitutions; of the remainder, most are small deletions (Sankaranarayanan, 1998; Elespuru and Sankaranarayanan, 2007).

Many genetic disorders (eg, cystic fibrosis, phenylketonuria, Tay-Sachs disease) are caused by the expression of recessive mutations. These mutations are mainly inherited from previous generations and are expressed when an individual inherits the mutant gene from both parents. New mutations make a larger contribution to the incidence of dominant diseases than to that of recessive diseases because only a single dominant mutation is required for expression. Thus, new dominant mutations are expressed in the first generation. If a dominant disorder is severe, its transmission between generations is unlikely because of reduced fitness. For dominants with a mild effect, reduced penetrance, or a late age of onset, the contribution from previous generations is undoubtedly larger than it is for mutations with severe early expression. Estimating the proportion of all Mendelian genetic diseases that can be ascribed to new mutations is not straightforward; a rough estimate is 20% (Shelby, 1994).

Besides causing diseases that exhibit Mendelian inheritance, gene mutations undoubtedly contribute to human disease through the genetic component of disorders with a complex etiology (Sankaranarayanan *et al.*, 1999; Sankaranarayanan, 2006). Some 3% (United Nations Scientific Committee on the Effects of Atomic Radiation [UNSCEAR], 2001) or 5% to 6% (Sankaranarayanan, 1998) of infants are affected by congenital abnormalities; if one includes multifactorial disorders that often have a late onset, such as heart disease, hypertension, and diabetes, the proportion of the population affected increases to more than 60% (Sankaranarayanan, 1998; UNSCEAR, 2001; Sankaranarayanan, 2006). Such frequencies are necessarily approximate because of differences among surveys in the reporting and classification of disorders. A higher prevalence would be found if less severe disorders were included in the tabulation. Nevertheless, such estimates provide a sense of the large impact of genetic disease.

Sensitive cytogenetic methods have led to the discovery of minor variations in chromosome structure that have no apparent effect. On the contrary, other relatively minor structural chromosome aberrations cause fetal death or serious abnormalities. Aneuploidy (gain or loss of one or more chromosomes) also contributes to fetal deaths and causes disorders such as Down syndrome. About four infants per 1000 live births have syndromes associated with chromosomal abnormalities, including translocations and aneuploidy. The majority of these syndromes (about 85%) result from trisomies (NRC, 2007a,b; Griffin, 1996; Nagaishi *et al.*, 2004). Most of the adverse effects of chromosomal abnormalities occur prenatally. It has been estimated that 5% of all recognized pregnancies involve chromosomal abnormalities, as do about 6% of infant deaths and 30% of all spontaneous embryonic and fetal deaths (Mohrenweiser, 1991; Nagaishi *et al.*, 2004). Among the abnormalities that have been observed, aneuploidy is the most common, followed by polyploidy. Structural aberrations constitute about 5% of the total. Unlike gene mutations, many of which are inherited from the previous generation, about 85% of the chromosomal anomalies observed in newborns arise de novo in the germ cells of the parents (Mohrenweiser, 1991). The frequency of aneuploidy assessed directly in human sperm, initially by standard karyotyping and more recently by fluorescence in situ hybridization

(FISH), is 3% to 4%; about 0.4% are sex chromosome aneuploidies (Martin *et al.*, 1991, 1996). The frequency of aneuploidy in human oocytes is about 18% (Martin *et al.*, 1991).

CANCER AND GENETIC RISK ASSESSMENTS

Cancer Risk Assessment

The formalized process for conducting a cancer risk assessment has many variations based on national requirements and regulations. A summary of some of the different approaches can be found in Moolenaar (1994). A recent approach developed by the European Commission under the acronym REACH (Registration, Evaluation, Authorisation and Restriction of Chemical Substances) aims to ensure that the necessary information is acquired to assess hazards and risks for human health for the very large number of chemicals for which little information is currently available (ec.europa.eu/environment/chemicals/reach/reach_intro.htm). There are also ongoing attempts, for example, by IPCS and the International Life Sciences Institute (ILSI) to develop a harmonized approach to cancer risk assessments. Although no totally unified approach is currently available, there is a framework that has been developed around a mode of action/human relevance concept that is discussed later in this section (Boobis *et al.*, 2006; Meek *et al.*, 2003). This framework, together with the formalized approach developed by the US Environmental Protection Agency (EPA) based on the paradigm presented by the National Research Council (NRC, 1983), is discussed here to depict the use of genetic toxicology in the risk assessment process.

Genetic toxicology data have been used until recently almost exclusively for hazard identification. Namely, if a chemical is DNA-reactive, then tumors are considered to be produced by this chemical via direct mutagenicity. This has led, in turn, to the use of the default linear extrapolation from the rodent bioassay tumor data to exposure levels consistent with human environmental or occupational exposures (EPA, 1986). The assessment of risk requires the application of a series of default options, for example, from laboratory animals to humans, from high to low exposures, from intermittent to chronic lifetime exposures, and from route to route of exposure. Default options are “generic approaches, based on general scientific knowledge and policy judgment that are applied to various elements of the risk assessment process when specific scientific information is not available” (NRC, 1994). The default options have been, in some ways, the Achilles heel of the cancer risk-assessment process because they have a very significant impact on low exposure risk but are based on an uncertain database. This concern led the EPA (1996) to develop a very different approach, initially described in the *Proposed Guidelines for Carcinogen Risk Assessment*, now released as the *Guidelines for Carcinogen Risk Assessment* (EPA, 2005). In these guidelines, the emphasis is on using mechanistic data, when available, to inform the risk assessment process, particularly for dose–response assessment and risk characterization. The goal is to develop biologically based or other forms of dose–response models for estimating cancer risk at low environmental exposures. This does, in general, bring the EPA approach into some harmony with those in other countries (Moolenaar, 1994), where a more narrative approach to risk assessment is preferred to a strictly quantitative one, and with the approaches described by IPCS (Boobis *et al.*, 2006) and ILSI (Meek *et al.*, 2003). The outcome of a more mechanistically based cancer risk assessment process is that there is a greater impetus to developing databases for key events in adverse outcome pathways and mechanisms of disease production

in addition to the yes/no output from genotoxicity assays in support of hazard identification. The same genotoxicity assays can be used for the collection of all these types of information, and the application of molecular biology techniques has certainly aided in the pursuit of mechanisms of mutagenicity and carcinogenicity. It is anticipated that the cancer risk assessment process will evolve as these new types of data are obtained.

Some of the issues that remain to be more firmly elucidated are (1) the relative sensitivities of different species (particularly rodent and human) to the induction of organ-specific mutations and tumors by chemicals and radiation; (2) the shape of the dose response for key events (eg, genetic alterations) in the formation of tumors and for the tumors themselves at low (environmental) exposure levels, especially for genotoxic chemicals; and (3) the relative sensitivity of susceptible subpopulations of all types. A better understanding of these major issues will greatly reduce the uncertainty in cancer risk assessments by, in part, replacing default options with biological data.

The most recent EPA guidelines for cancer risk assessment (EPA, 2005) provide a framework for cancer risk assessment that utilizes a mode-of-action (MoA) as the means of describing the “necessary but not sufficient” steps required for a chemical to produce a tumor. A particular MoA can further be defined by a set of key events that are required for tumor development (Preston and Williams, 2005). In addition, the key events can be used to establish whether or not a particular MoA described for a rodent model is plausible in humans (the so-called Human Relevance Framework, Meek *et al.*, 2003; Boobis *et al.*, 2006). This more defined approach based on the use of the best available science can possibly be extended to include noncancer health effects (Seed *et al.*, 2005; Boobis *et al.*, 2008).

Genetic Risk Assessment

The approach for conducting a genetic risk assessment is less well defined than that for cancer risk. In fact, only a handful of genetic risk assessments have been conducted. An in-depth discussion of the topic can be found in the book *Methods for Genetic Risk Assessment* (Brusick, 1994). The reader is also referred to the genetic risk for ethylene oxide developed by the EPA (Rhombert *et al.*, 1990) and the discussion of this and a recalculation presented by Preston *et al.* (1995). These two articles serve to highlight the difficulties with and uncertainties in genetic risk assessments.

The general approach is to use rodent germ cell and somatic cell data for induced genetic alterations and human data for induced genetic alterations in somatic cells (when available) to estimate the frequency of genetic alterations in human germ cells. This is the “parallelogram approach” (Fig. 9-1) first used by Brewen and Preston (1974) for X-irradiation and subsequently more fully developed for chemical exposures by Sobels (1982). The aim of this approach is to develop two sensitivity factors: (1) somatic to germ cell in the rodent and (2) rodent to human using somatic cells. These factors can then be used to estimate genetic alterations in human germ cells. Of course, for a complete estimate of genetic risk, it is necessary to obtain an estimate of the frequency of genetic alterations transmitted to the offspring (UNSCEAR, 2001). In addition, separate genetic risk assessments need to be conducted for males and females, given the considerable difference in germ cell development and observed and predicted sensitivity differences. Of particular note with regard to genetic risk assessment, to date there has been no unequivocal demonstration of an effect that can be detected in the children following parental exposure for chemicals or ionizing radiation.

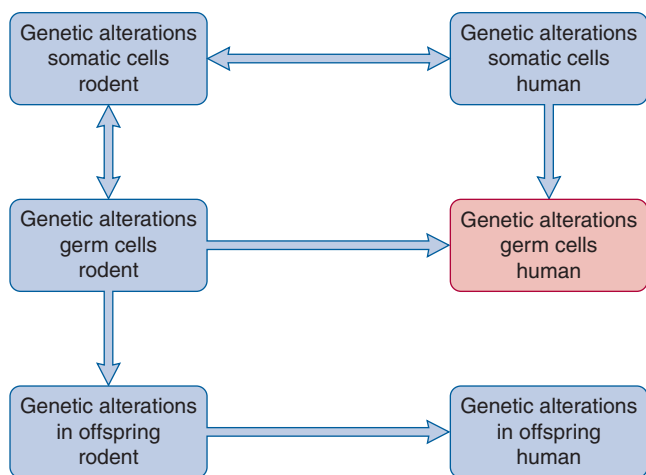

Figure 9-1. Parallelogram approach for genetic risk assessment. Data obtained for genetic alterations in rodent somatic and germ cells and human somatic cells are used to estimate the frequency of the same genetic alterations in human germ cells. The final step is to estimate the frequency of these genetic alterations that are transmitted to offspring.

MECHANISMS OF INDUCTION OF GENETIC ALTERATIONS

DNA Damage

The types of DNA damage produced by ionizing radiations, non-ionizing radiations, and chemicals are many and varied, including single- and double-strand breaks in the DNA backbone, cross-links between DNA bases or between DNA bases and proteins, and chemical addition to the DNA bases (adducts) (Fig. 9-2). The aim of this section is to introduce the topic of DNA damage because such damage is the substrate for the formation of genetic alterations and genotoxicity in general. However, much greater detail can be found in recent reviews that are referenced at the appropriate places within each section. It should be noted that endogenous processes and exogenous agents can produce DNA damage, but mutations themselves are produced by errors in DNA repair or replication that are a consequence of the induced DNA damage.

Ionizing Radiations Ionizing radiations such as x-rays, γ -rays, and α particles produce DNA single- and double-strand breaks and a broad range of base damages from oxidative processes (Goodhead, 1994; Wallace, 1994; Ward, 1994; Cadet *et al.*, 2010). In addition, recent evidence indicates that multiply damaged sites or clustered lesions can be formed that appear to be more difficult to repair (Eccles *et al.*, 2011). Such lesions consist of multiple single lesions, including oxidized purine or pyrimidine bases, sites of base loss, and single-strand breaks. These multiple lesions can be formed in DNA from the same radiation energy deposition event (Blaisdell *et al.*, 2001). The relative proportions of these different classes of DNA damage vary with type of radiation. For example, single-strand breaks and base damages predominate with x-rays, for which ionization density is sparse, whereas the frequencies of single- and double-strand breaks are more similar with α particles, for which ionization is dense. The frequencies of individual base damages have been assessed using monoclonal antibodies, for example (Le *et al.*, 1998), but only a very few of the total spectrum of lesions have so far been studied. More recently, it has been demonstrated that the modified histone γ -H2AX can be used as a sensitive marker of DNA double-strand breaks (Nakamura *et al.*, 2006; Mah *et al.*, 2010).

Ultraviolet Light Ultraviolet light (a nonionizing radiation) induces two predominant lesions, cyclobutane pyrimidine dimers and 6,4-photoproducts. These lesions have been studied extensively because they can be quantitated by both chemical and immunological methods (Friedberg *et al.*, 1995). In part because of this feature, the repair of cyclobutane dimers and 6,4-photoproducts has been well characterized, as discussed below.

Chemicals Chemicals can produce DNA alterations either directly (DNA-reactive) by forming adducts or indirectly by intercalation of the chemical between the base pairs (see Heflich, 1991, for a review). Intercalation of acridine compounds (eg, 9-aminoacridine) and other planar molecules in repetitive DNA sequences has long been associated with the induction of frameshift mutations in which one or two base pairs have been gained or lost (Ferguson and Denny, 1990; Hoffmann *et al.*, 2003). Many electrophilic chemicals react with DNA, forming covalent addition products (adducts). The DNA base involved and the positions on DNA bases can be specific for a given chemical. Such specificity of DNA damage can result in a spectrum of mutations that is chemical specific, that is, a fingerprint of sorts (Dogliotti *et al.*, 1998; Jarabek *et al.*, 2009). Some alkylated bases can mispair, causing mutations when DNA is replicated. Alkylated bases can also lead to secondary alterations in DNA. For example, the alkyl group of an *N*⁷-alkylguanine adduct, which is a major adduct formed by many alkylating agents, labilizes the bond that connects the base to deoxyribose, thereby stimulating base loss. Base loss from DNA leaves an apurinic or apyrimidinic site, commonly called an AP site. The insertion of incorrect bases into AP sites causes mutations (Laval *et al.*, 1990).

Bulky DNA adducts formed, for example, by metabolites of benzo(*a*)pyrene or *N*-2-acetylaminofluorene are recognized by the cell in a similar way to UV damages and are repaired similarly (see below). Such adducts can also hinder polymerases and cause mutation as a consequence of errors that they trigger in replication.

Endogenous Agents Endogenous agents are responsible for several hundred DNA damages per cell per day (Lindahl, 2000). The majority of these damages are altered DNA bases (eg, 8-oxoguanine and thymine glycol) and AP sites. The cellular processes that can lead to DNA damage are oxygen consumption that results in the formation of reactive oxygen species (eg, superoxide O_2^- , hydroxyl free radicals $\cdot OH$, and hydrogen peroxide) and deamination of cytosine and 5-methylcytosine leading to uracil and thymine, respectively. The process of DNA replication itself is somewhat error-prone, and an incorrect base can be added by replication polymerases (one in about 10^6 bases replicated). However, the frequency of misinserted bases in replication is not the sole determinant of the spontaneous mutation frequency. Living cells reduce the rate of polymerase error appreciably through error recognition and repair processes (Johnson, 2010). A high-fidelity polymerase may make one error in a million bases while copying roughly 300 base pairs per second, but polymerase proofreading and mismatch correction then lower the error rate as much as 1000-fold (Johnson, 2010). The result is a low spontaneous mutation rate. A recent study based on the sequencing of 19 *Escherichia coli* genomes in a 40,000-generation experiment estimated the rate of spontaneous base pair substitutions to be 8.9×10^{-11} per base pair per generation (Wielgoss *et al.*, 2011). Despite the fidelity of these biological processes, the frequencies of endogenously produced DNA damages can be increased by exogenous (genotoxic) agents (Swenberg *et al.*, 2011).

Figure 9-2. Spectrum of DNA damage induced by physical and chemical agents.

DNA Repair

The cell is faced with the problem of how to cope with the quite extensive DNA damage that it sustains. In a general sense, two processes are present to achieve this. If the damage is extensive, the cell can undergo apoptosis (programmed cell death), effectively avoiding its becoming a mutant cell (Evan and Littlewood, 1998). If the damage is less severe, it can be repaired by a range of processes that are part of a generalized cellular DNA damage response network that returns the DNA to its undamaged state (error-free repair) or to an improved but still altered state (error-prone repair). As a feature of this error-prone repair, it has been demonstrated that a family of polymerases, the eukaryotic translesion synthesis polymerases (eg, human Y-family polymerases η , ι , κ , and Rev1), can bypass lesions that otherwise would

block replication by the normal processive polymerases (Rattray and Strathern, 2003; Prakash *et al.*, 2005). These polymerases have the ability to bypass specific DNA lesions or groups of lesions. The result of the bypass can be an incorrect DNA sequence or a correct one depending on the induced lesion and the particular bypass polymerase. The basic principles underlying most repair processes (but not translesion synthesis) are damage recognition, followed by either direct reversal of the damage (eg, sealing of strand breaks or cleavage of pyrimidine dimers) or removal of the damage, repair DNA synthesis, and ligation. In order to achieve this for different types of DNA lesions, cells have modified the protein complexes used for other housekeeping processes (eg, transcription, replication, and recombination). This chapter presents a brief outline of the major classes of DNA repair; much greater detail can be found

in the reviews provided for each section and general reviews by Van Houten and Albertini (1995), Friedberg (2000), Wood *et al.* (2005), and Bansbach and Cortez (2011).

Base Excision Repair The major pathways by which DNA base damages are repaired involve a glycosylase that removes the damaged base, causing the production of an apurinic or apyrimidinic site that can be filled by the appropriate base or processed further (Dempfle and Harrison, 1994; Seeberg *et al.*, 1995; Wood, 1996; McCullough *et al.*, 1999; Sung and Dempfle, 2006). The resulting gap from this further processing can be filled by a DNA polymerase, followed by ligation to the parental DNA. The size of the gap is dependent on the particular polymerase involved in the repair (ie, polymerase β for short patches; polymerase δ or ϵ for longer patches). Oxidative damage, either background or induced, are important substrates for base excision repair (Lindahl, 2000). The role of translesion bypass polymerases in the repair of DNA base alterations is discussed above.

Nucleotide Excision Repair The nucleotide excision repair (NER) system provides the cell's ability to remove bulky lesions from DNA. In the past decade the NER process has been studied extensively, and a complete characterization of the genes and proteins involved has been obtained (Reardon and Sancar, 2006; Reed, 2011). NER uses about 30 proteins to remove a damage-containing oligonucleotide from DNA. The basic steps are damage recognition, incision, excision, repair synthesis, and ligation. The characterization of these steps has been enhanced by the use of rodent mutant cell lines and cells from individuals with the UV-sensitivity, skin cancer-prone syndrome xeroderma pigmentosum (XP, for which there are at least seven distinct genetic complementation groups). Of particular interest is the link between NER and transcription, for which the DNA damage in actively transcribing genes, and specifically the transcribed strand, is preferentially and thus more rapidly repaired than the DNA damage in the rest of the genome (Lommel *et al.*, 1995; Jiang and Sancar, 2006). Thus, the cell protects the integrity of the transcription process. This link between transcription and repair appears to be provided by two factors: (1) when a bulky lesion is located on the transcribed strand of an active gene, RNA polymerase II is blocked, thus providing a signal for recruiting the NER complex, and (2) a major component of the NER complex is the TFII H basal transcription factor. The involvement of TFII H in repair also provides some specificity to the incisions in the DNA required to remove the damaged nucleotide. An incision on the 3' side of the damage is made first by the XPG protein followed by 1 on the 5' side by the XPF-ERCC1 complex. The lesion is removed in the 27- to 30-nucleotide segment formed by the two incisions. The gap is filled by polymerase δ or ϵ in the presence of replication factor C and proliferating cell nuclear antigen (PCNA). Ligation by DNA ligase I completes the process. This NER process has been reconstituted *in vitro*, allowing for complete characterization, kinetic studies, and estimates of fidelity (Aboussekhra *et al.*, 1995).

Double-Strand Break Repair Cell survival is seriously compromised by the presence in the cell of broken chromosomes. Unrepaired double-strand breaks trigger one or more DNA damage response systems to either check cell-cycle progression or induce apoptosis. In order to reduce the probability of persistent DNA double-strand breaks, cells have developed an array of specific repair pathways. These pathways are largely similar across a broad range of species from yeast to humans, although the most frequently used one is different among species. There are two general pathways for repair of DNA double-strand breaks: homologous recombination

and nonhomologous end-joining. These two can be considered as being in competition for the double-strand break substrate (Haber, 2000; Sonoda *et al.*, 2006; Mladenov and Iliakis, 2011).

Homologous Recombination Eukaryotes undergo homologous recombination as part of their normal activities both in germ cells (meiotic recombination) and somatic cells (mitotic recombination) Zheng *et al.*, 2011. The repair of double-strand breaks (and single-strand gaps) basically uses the same process and complex of proteins, although some different protein-protein interactions are involved (Shinohara and Ogawa, 1995). In eukaryotes, the process has been characterized most extensively for yeast, but evidence is accumulating that a very similar process occurs in mammalian cells, including human (Johnson *et al.*, 1999; Cahill *et al.*, 2006). The basic steps in double-strand break repair are as follows. The initial step is the production of a 3'-ended single-stranded tail by exonucleases or helicase activity. Through a process of strand invasion, whereby the single-stranded tail invades an undamaged homologous DNA molecule, together with DNA synthesis, a so-called Holliday junction DNA complex is formed. By cleavage of this junction, two DNA molecules are produced (with or without a structural crossover), neither of which now contain a strand break. Additional models have been proposed but probably play a minor role in mammalian cells (Haber, 2000). A detailed description of the specific enzymes known to be involved can be found in Shinohara and Ogawa (1995), Cahill *et al.* (2006), and Hiom (2010).

Nonhomologous End-Joining The characterization of nonhomologous end-joining (NHEJ) in mammalian cells was greatly enhanced by the observation that mammalian cell lines that are hypersensitive to ionizing radiation are also defective in the V(D)J recombination process, which is the means by which the huge range of an antibody's antigen-binding sites and T-cell receptor proteins are generated during mammalian lymphoid cell development. V(D)J recombination requires the production of double-strand breaks, recombination of DNA pieces, and subsequent religation. A major component of the NHEJ repair complex is a DNA-dependent protein kinase (DNA-PK). This protein, a serine/threonine kinase, consists of a catalytic subunit (DNA-PK_{cs}) and a DNA-end-binding protein consisting of KU70 and KU80 subunits. The specific role of DNA-PK in the repair of double-strand breaks is unclear in mammalian cells; a detailed discussion of what is known and some possible models of NHEJ are presented in the reviews by Critchlow and Jackson (1998) and Burma *et al.* (2006). Perhaps the most viable role of DNA-PK is to align the broken DNA ends to facilitate their ligation. It also appears that DNA-PK helps in the selection of the specific repair pathway that is ultimately used for repair (Neal and Meek, 2011). In addition, DNA-PK might serve as a signal molecule for recruiting other repair proteins known to be involved in yeast and to some extent in mammalian cells. The final ligation step is performed by DNA ligase IV in human cells.

Mismatch Repair The study of DNA mismatch repair systems has received considerable attention over the past few years, in part, because an association has been demonstrated between genetic defects in mismatch repair genes and the genomic instability associated with cancer susceptibility syndromes and sporadic cancers. In general, DNA mismatch repair systems operate to repair mismatched bases formed during DNA replication, genetic recombination, and as a result of DNA damage induced by chemical and physical agents. Detailed reviews can be found in Kolodner (1995), Jiricny (1998), Modrich and Lahue (1996), and Jun *et al.* (2006).

The principal steps in all cells from prokaryotes to human are damage recognition by a specific protein that binds to the mismatch,

stabilizing of the binding by the addition of one or more proteins, cutting the DNA at a distance from the mismatch, excision past the mismatch, resynthesis, and ligation. In some prokaryotes, the cutting of the DNA (for DNA replication mismatches) is directed to the strand that contains the incorrect base by using the fact that recently replicated DNA is unmethylated at *N*⁶-methyladenine at a GATC sequence. The question of whether or not strand-specific mismatch repair occurs in mammalian cells has not been resolved, although evidence does point to its occurrence (Modrich, 1997; Mastrocola and Heinen, 2010). Strand specificity for DNA mismatches resulting from induced DNA damage has not been identified.

***O*⁶-Methylguanine-DNA Methyltransferase Repair** The main role for *O*⁶-methylguanine-DNA methyltransferase (MGMT) is to protect cells against the toxic effects of simple alkylating agents. The methyl group is transferred from *O*⁶-methylguanine in DNA to a cysteine residue in MGMT. The adducted base is reverted to a normal one by the enzyme, which is itself inactivated by the reaction. Details of the MGMT enzyme properties and the gene isolation and characterization can be found in Tano *et al.* (1990), Grombacher *et al.* (1996), and Margison *et al.* (2003).

The probability that induced DNA damage can be converted into a genetic alteration is influenced by the particular repair pathways recruited, the rate of repair of the damage, and the fidelity and completeness of the repair. The mechanisms of induction of gene mutations and chromosome alterations discussed in the following sections build upon the assessment of the probability of repair versus misrepair versus nonrepair that can be derived from a knowledge of the mechanism of action of the different DNA repair mechanisms. The preceding sections, together with the references provided, should assist in this assessment.

Formation of Gene Mutations

Somatic Cells Gene mutations are considered to be small DNA sequence changes confined to a single gene; larger genomic changes are considered below, under the section “Formation of Chromosomal Alterations.” The general classes of gene mutations are base substitutions and small additions or deletions. More detailed classifications can be found in the review by Ripley (1991). Base substitutions are the replacement of the correct nucleotide by an incorrect one; they can be further subdivided as transitions where the change is purine for purine or pyrimidine for pyrimidine, and transversions where the change is purine for pyrimidine and vice versa. Frameshift mutations are strictly the addition or deletion of one or a few base pairs (not in multiples of three) in protein-coding regions. The definition is more generally expanded to include such additions and deletions in any DNA region. For the discussion of the mechanism of induction of gene mutations and chromosomal alterations, it is necessary to distinguish chemicals by their general mode of action. Chemicals that can produce genetic alterations with similar effectiveness in all stages of the cell cycle are called radiomimetic because they act like radiation in this regard. Chemicals that produce genetic alterations far more effectively in the S phase of the cell cycle are described as nonradiomimetic. The great majority of chemicals are nonradiomimetic; the radiomimetic group includes bleomycin, streptonigrin, neocarzinostatin, and 8-ethoxycaffeine.

Gene mutations can arise in the absence of specific exogenous exposures to radiation and chemicals. The great majority of so-called spontaneous (background) mutations arise from *replication* of an altered template. The DNA alterations that arise are either the result of oxidative damage or produced from the deamination

of 5-methylcytosine to thymine at CpG sites resulting in G:C → A:T transitions. Mutations induced by ionizing radiations tend to be deletions ranging in size from a few bases to multilocus events (Thacker, 1992). The rapid rate of repair of the majority of radiation-induced DNA damages greatly reduces the probability of DNA lesions being present at the time of DNA replication. Thus, mutations induced by ionizing radiations are generally the result of errors of *DNA repair* (Preston, 1992). The low frequencies of gene mutations are produced from any unrepaired DNA base damage present during DNA replication.

Gene mutations produced by a majority of chemicals and non-ionizing radiations are base substitutions, frameshifts, and small deletions. Of these mutations, a very high proportion is produced by errors of *DNA replication* on a damaged template. Thus, the probability of a DNA adduct, for example, being converted into a mutation is determined, to a significant extent by the number of induced DNA adducts that remain in the DNA at the time that it is replicated and by the nature of the adduct itself (Jarabek *et al.*, 2009). Thus, relative mutation frequency will be the outcome of the race between repair and replication, that is, in general terms, the more repair that takes place prior to replication, the lower the mutation frequency for a given amount of induced DNA damage. Significant regulators of the race are cell cycle checkpoint genes (eg, *P53*) because if the cell is checked from entering the S phase at a G₁/S checkpoint, more repair can take place prior to the cell starting to replicate its DNA (Mercer, 1998; Giglia-Mari *et al.*, 2011).

The proportion of chemically induced gene mutations that result from DNA repair errors is low, given that the DNA repair processes, unlike translesion synthesis, are typically error-free. Moreover, repair of chemically induced DNA damage is generally slower than for ionizing radiation damage, for which the balance tips toward replication prior to repair, especially for cells in the S phase at the time of exposure. In the case of translesion bypass, discussed above, gene mutations can be produced at relatively high frequencies.

Germ Cells The mechanism of production of gene mutations in germ cells is basically the same as in somatic cells. Ionizing radiations produce mainly deletions via errors of DNA repair; the majority of chemicals induce base substitutions, frameshifts, and small deletions by errors of DNA replication (Favor, 1999).

An important consideration for assessing gene mutations induced by chemicals in germ cells is the relationship between exposure and the timing of DNA replication. Fig. 9-3 depicts the stages in oogenesis and spermatogenesis. A few features are worthy of note. The spermatogonial stem cell in humans and rodents has a long cell cycle time, eight days or longer, with only a small fraction being occupied by the S phase. Thus, the probability of DNA repair taking place prior to DNA replication is high, for both acute and chronic treatments. However, for considerations of genetic risk, it is the spermatogonial stem cell that is the major contributor because it is present, in general, throughout the reproductive lifetime of an individual. Each time a spermatogonial stem cell divides it produces a differentiating spermatogonium and a stem cell. Thus, the stem cell can accumulate genetic damage from chronic exposures. Differentiating spermatogonia, as far as the induction of gene mutation is concerned, are the same as mitotically dividing somatic cells.

The first S phase after gametogenesis occurs in the zygote, formed by fertilization. This fact needs to be balanced by the lack of DNA repair in late spermatids and sperm. Thus, DNA damage induced in these stages will remain until the zygote. Postmeiotic germ cells are particularly sensitive to mutation induction by

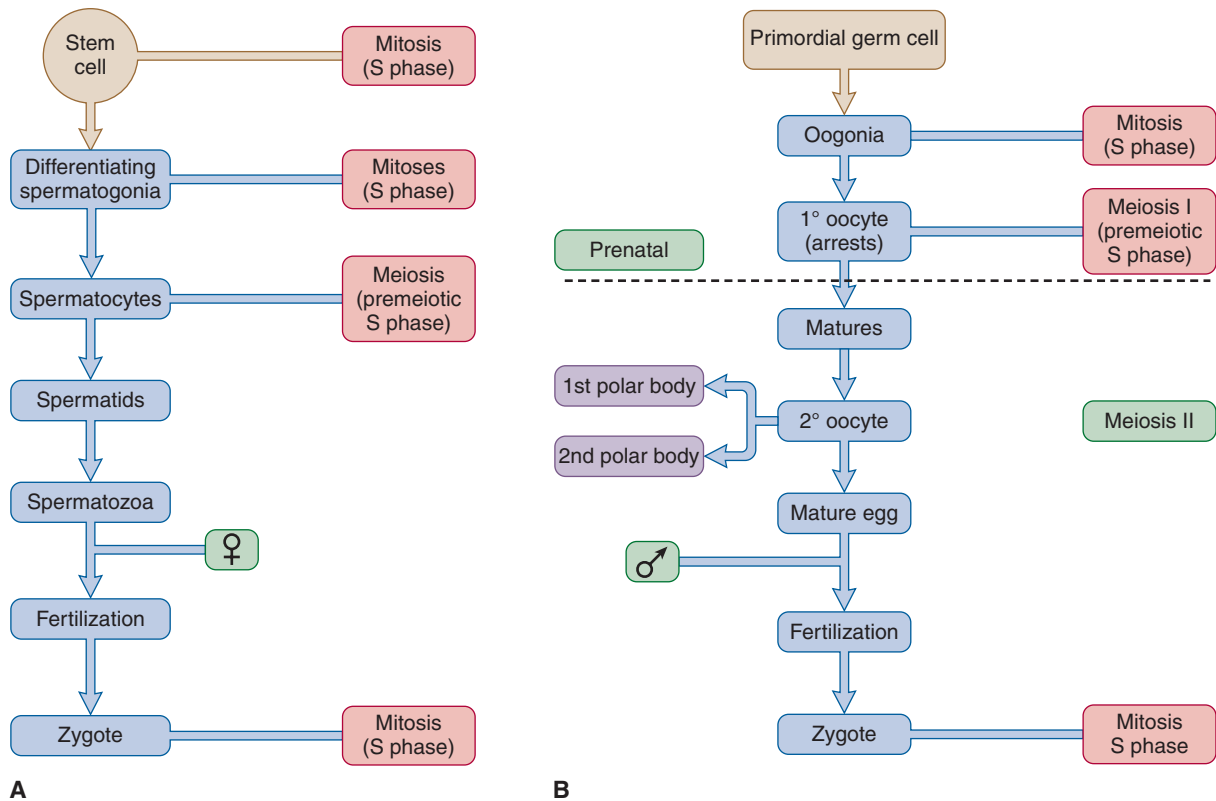

Figure 9-3. The stages of spermatogenesis (A) and oogenesis (B) indicating the periods of cell division and DNA replication (S phase).

nonradiomimetic chemicals, especially following acute exposures (Russell, 2004). The fairly short duration of this stage (approximately 21 days in the mouse) means that their contribution to genetic risk following chronic exposures is quite small.

For oogenesis (Fig. 9-3) similar observations on gene mutation induction and timing of S phase can be made. In this case the primary oocyte arrests prior to birth, and there is no further S phase until the zygote. For this reason, the oocyte is resistant to the induction of gene mutations by nonradiomimetic chemicals but not to radiation, for which DNA repair is the mode of formation of mutations, and DNA repair occurs in oocytes (Brewen and Preston, 1982).

These mechanistic aspects of the production of gene mutations (and chromosome alterations described in the following two sections) by chemicals and radiation in somatic and germ cells are most important for considerations of the design of genetic toxicology assays, the interpretation of the data generated, and the incorporation of the data into cancer and genetic risk assessments.

Formation of Chromosomal Alterations

Somatic Cells

Structural Chromosome Aberrations There are components of the formation of chromosome aberrations, SCEs (the apparently reciprocal exchange between the sister chromatids of a single chromosome), and gene mutations that are similar. In particular, damaged DNA serves as the substrate leading to all these events. However, chromosome aberrations induced by ionizing radiations are generally formed by errors of DNA repair, whereas those produced by nonradiomimetic chemicals are generally formed by errors of DNA replication on a damaged DNA template.

The DNA repair errors that lead to the formation of chromosome aberrations following ionizing radiation (and radiomimetic

chemical) exposure arise from misligation of double-strand breaks or interaction of coincidentally repairing regions during NER of damaged bases. The details of the DNA damage types and their repair are described in the previous section. Thus, the overall kinetics and fidelity of DNA repair influence the sensitivity of cells to the induction of chromosomal aberrations produced by misrepair. The broad outcomes of misrepair are that incorrect rejoining of chromosomal pieces during repair leads to chromosomal exchanges within (eg, inversions and interstitial deletions) and between (eg, dicentric and reciprocal translocations) chromosomes. In fact, using FISH, it can be shown that very complex rearrangements take place (Anderson *et al.*, 2000). Failure to rejoin double-strand breaks or to complete repair of other types of DNA damage leads to terminal deletions.

Acentric fragments arise from interstitial deletions, terminal deletions, and the formation of dicentric chromosomes and rings. The failure to incorporate an acentric fragment into a daughter nucleus at anaphase/telophase, or the failure of a whole chromosome to segregate at anaphase to the cellular poles, can result in the formation of a membrane-bound micronucleus that resides in the cytoplasm.

Errors of DNA replication on a damaged template can lead to a variety of chromosomal alterations. The majority of these involve deletion or exchange of individual chromatids (chromatid-type aberrations). Thus, nonradiomimetic chemicals induce only chromatid-type aberrations, whereas radiations and radiomimetic chemicals induce chromatid-type aberrations in the S and G₂ phases of the cell cycle, but chromosome-type aberrations affecting both chromatids in G₁. The reason for this latter observation is that the G₁ (or G₀) chromosome behaves as a single DNA molecule and aberrations formed in it will be replicated in the S phase and will involve both chromatids. This distinction is important for considerations of outcome of the aberrations and the probability

of an effect on cells because for chromatid-type aberrations, one chromatid remains intact and genetically unaltered, in contrast to chromosome-type aberrations in which both chromatids are damaged (Preston *et al.*, 1995).

Numerical Chromosome Changes Numerical changes (eg, monosomies, trisomies, and ploidy changes) can arise from errors in chromosomal segregation. The complexity of the control and the mechanics of the mitotic process means that alteration of various cellular components can result in failure to segregate the sister chromatids to separate daughter cells or in failure to segregate a chromosome to either pole (Bickel and Orr-Weaver, 1996; Preston, 1996; Hunt, 2006). The mechanisms underlying chromosomal loss are pertinent to those involved in the formation of micronuclei.

A limited set of chemicals has been demonstrated to cause aneuploidy through interaction with components of the structures that facilitate chromosome movement (Preston, 1996; Aardema *et al.*, 1998). These include benomyl, griseofulvin, nocodazole, colchicine, colcemid, vinblastine, and paclitaxel. These chemicals affect tubulin polymerization or spindle microtubule stability. To date, other mechanisms of aneuploidy induction by chemicals have not been firmly identified.

Sister Chromatid Exchanges SCEs are produced during the S phase and are presumed to be a consequence of errors in the replication process, perhaps at the sites of stalled replication complexes (Painter, 1980; Heartlein *et al.*, 1983; Preston, 1991; Wilson and Thompson, 2007). Because SCEs are apparently reciprocal exchanges, it is quite possible that they result from a recombination process occurring at the site of the stalled replication fork. It is, in fact, this mode of action that makes assays for SCE less than ideal for detecting effects due directly to a chemical exposure. For example, the creation of intracellular conditions that slow the progress of DNA replication could lead to the formation of SCE.

Germ Cells The formation of chromosomal alterations in germ cells is basically the same as that for somatic cells, namely, via mis-repair for ionizing radiations and radiomimetic chemicals for treatments in G₁ and G₂, and by errors of replication for all radiations and chemicals for DNA damage present during the S phase. Also, the restrictions on the timing of formation of chromosomal alterations induced by nonradiomimetic chemicals in germ cells is as described above for gene mutations, namely at the specific stages where DNA synthesis occurs, as depicted in Fig. 9-3.

The types of aberrations formed in germ cells are the same as those formed in somatic cells (eg, deletions, inversions, translocations), although their appearance in diplotene/diakinesis of meiosis I, where analysis is frequently conducted, is rather different because of the homologous chromosome pairing that takes place in meiotic cells (see the review by Léonard, 1973). The specific segregation of chromosomes during meiosis influences the probability of recovery of an aberration, particularly a reciprocal translocation, in the offspring of a treated parent. This is discussed in detail in Preston *et al.* (1995).

ASSAYS FOR DETECTING GENETIC ALTERATIONS

Introduction to Assay Design

Genetic toxicology assays are used to identify germ cell mutagens, somatic cell mutagens, and potential carcinogens. These assays can detect diverse kinds of genetic alterations (eg, gene mutations,

Table 9-1

Principal Assays in Genetic Toxicology

- I. Pivotal assays
 - A. A well-characterized assay for gene mutations
The *Salmonella*/mammalian microsome assay (Ames test)
 - B. A mammalian assay for chromosome damage in vivo: metaphase analysis in rodent bone marrow or micronucleus assay in rodent bone marrow or blood
- II. Other assays offering an extensive database or unique genetic endpoint
 - A. Assays for gene mutations
E coli WP2 tryptophan reversion assay
TK or *HPRT* forward mutation assays in cultured mammalian cells
Drosophila sex-linked recessive lethal assay
Gene-mutation assays in rodent somatic cells or transgenic animals
 - B. Cytogenetic analysis in cultured Chinese hamster or human cells
Assays for chromosome aberrations and micronuclei
Assays for aneuploidy
 - C. Other indicators of genetic damage
Mammalian DNA damage and repair assays
Mitotic recombination assays in yeast and *Drosophila*
 - D. Mammalian germ cell assays
Mouse specific-locus tests
Cytogenetic analysis and heritable translocation assays
DNA damage and repair in rodent germ cells
Mutation analysis in tandem-repeat loci in mice

chromosome aberrations, and aneuploidy) that are relevant to the production of adverse human health outcomes. Over the last three decades, hundreds of chemicals and complex mixtures have been evaluated for genotoxic effects. Genetic toxicology assays serve two interrelated but distinct purposes in the toxicologic evaluation of chemicals: (1) identifying mutagens for purposes of hazard identification and (2) characterizing dose–response relationships and mutagenic mechanisms, both of which contribute to an understanding of genetic and carcinogenic risks.

A common experience when surveying the genetic toxicology literature is encountering a bewildering array of assays in viruses, bacteria, fungi, cultured mammalian cells, plants, insects, and mammals. More than 200 assays for mutagens have been proposed, and useful information has been obtained from many of them. Although most genetic toxicology testing and evaluation relies on relatively few assays, data from relatively obscure assays can sometimes contribute to a judgment about the genetic activity of a compound.

Table 9-1 lists key assays that have a prominent place in genetic toxicology. Table 9-2 is a more comprehensive list that provides literature citations to many of the assays that one might encounter in the genetic toxicology literature. Even this extensive table is not exhaustive, in that it emphasizes methods in applied genetic toxicology and not those assays whose use has been largely restricted to studies of mutational mechanisms. The commonly used assays rely on phenotypic effects as indicators of gene mutations or small deletions and on cytological methods for observing

Table 9-2

Overview of Genetic Toxicology Assays

ASSAYS	SELECTED LITERATURE CITATIONS
I. Prediction of genotoxicity	
A. Interpretation of chemical structure Structural alerts to genotoxicity	Ashby, (1994), Ashby and Tennant (1991), Ashby and Paton (1993)

Mouse bone marrow micronucleus assay with centromere labeling	Adler (1993), Aardema <i>et al.</i> (1998), Krishna and Hayashi (2000)
VII. Germ cell mutagenesis	
A. Measurement of DNA damage	
Molecular dosimetry based on mutagen adducts in reproductive cells	Russell and Shelby (1985), Olsen <i>et al.</i> (2010), Verhofsrad <i>et al.</i> (2011)
UDS in rodent germ cells	Bentley <i>et al.</i> (1994), Sotomayor and Segá (2000)
Alkaline elution assays for DNA strand breaks in rodent testes	Bentley <i>et al.</i> (1994)
Comet assay in sperm and gonadal tissue	Speit <i>et al.</i> (2009)
B. Gene mutations	
Mouse specific-locus test for gene mutations and deletions	Russell <i>et al.</i> (1981), Ehling (1991), Russell and Russell (1992), Favor (1999), Russell (2004), Singer <i>et al.</i> (2006)
Mouse electrophoretic specific-locus test	Lewis (1991)
Dominant mutations causing mouse skeletal defects or cataracts	Ehling (1991), Selby <i>et al.</i> (2004)
ESTR assay in mice	Yauk (2004), Dubrova (2005), Singer <i>et al.</i> (2006), Somers (2006)
Germ cell mutations in transgenic assays	Lambert <i>et al.</i> (2005), Singer <i>et al.</i> (2006)
C. Chromosomal aberrations	
Cytogenetic analysis of oocytes, spermatogonia, spermatocytes, or zygotes	Kirkland <i>et al.</i> (1990), Tease (1992), Russo (2000), Marchetti <i>et al.</i> (2001)
Direct detection in sperm by FISH	Marchetti <i>et al.</i> (2006, 2008)
Micronuclei in mouse spermatids	Russo (2000), Hayashi <i>et al.</i> (2007)
Mouse heritable translocation test	Russell and Shelby (1985), Singer <i>et al.</i> (2006)
D. Dominant lethal mutations	
Mouse or rat dominant lethal assay	Adler <i>et al.</i> (1994), Singer <i>et al.</i> (2006)
E. Aneuploidy	
Cytogenetic analysis for aneuploidy arising by nondisjunction	Allen <i>et al.</i> (1986), Adler (1993), Adler <i>et al.</i> (1994), Aardema <i>et al.</i> (1998), Russo (2000), Marchetti <i>et al.</i> (2001)
Sex chromosome loss test for nondisjunction or breakage	Russell and Shelby (1985)
Micronucleus assay in spermatids with centromere labeling	Aardema <i>et al.</i> (1998)
FISH with probes for specific chromosomes in sperm	Russo (2000), Marchetti <i>et al.</i> (2006, 2008)

gross chromosomal damage. Detailed information on assay design, testing data, controls, sample sizes, and other factors in effective testing is found in the references cited.

Some assays for gene mutations detect forward mutations whereas others detect reversion. Forward mutations, such as those detected in the thymidine kinase gene (*tk*) in the widely used assay in mouse lymphoma cells (Clements, 2000; Wang *et al.*, 2009), are genetic alterations in a wild type gene that are detected by a change in phenotype caused by the alteration or loss of gene function. In contrast, back mutations are mutations that restore gene function in a mutant, such as the histidine revertants detected in the Ames assay in *Salmonella* (Ames *et al.*, 1975; Mortelmans and Zeiger, 2000; Claxton *et al.*, 2010). Thus, a back mutation or reversion that restores gene function in a mutant brings about a return to the

wild type phenotype. In principle, forward-mutation assays should respond to a broad spectrum of mutagens because any mutation that interferes with gene expression should confer the detectable phenotype. A reversion assay might be expected to have a more restricted mutational response because only mutations that correct or compensate for the specific mutation in a particular mutant will be detected. In fact, some reversion assays respond to a broader spectrum of mutational changes than one might expect because mutations at a site other than that of the original mutation, either within the test gene or in a different gene (ie, a suppressor mutation), can sometimes confer the selected phenotype. Both forward mutation assays and reversion assays are used extensively in genetic toxicology.

The simplest gene mutation assays rely on selection techniques to detect mutations. A selection technique is a means of imposing

experimental conditions under which only cells or organisms that have undergone mutation can grow. For example, only cells that have a mutation in the *tk* gene can grow in medium containing the inhibitory chemical trifluorothymidine (Seifried *et al.*, 2006; Wang *et al.*, 2009). Selection techniques greatly facilitate the identification of rare cells that have experienced mutation among the many cells that have not. Forward mutations (Clements, 2000; Vlasakova *et al.*, 2005) and reversions (Josephy, 2000; Mortelmans and Riccio, 2000; Mortelmans and Zeiger, 2000; Kamber *et al.*, 2009) can both be detected by selection techniques in microorganisms and cultured mammalian cells. Because of their speed, low cost, and ease of detecting events that occur at low frequency (ie, mutation), assays in microorganisms and cell cultures have figured prominently in genetic toxicology.

Studying mutagenesis in intact animals requires assays of more complex design than the simple selection methods used in microorganisms and cultured cells. Genetic toxicology assays therefore range from inexpensive short-term tests (Zeiger, 2010) that can be performed in a few days to complicated assays for mutations in mammalian germ cells (Favor, 1999; Russell, 2004; Singer *et al.*, 2006). Even in multicellular organisms, there has been an emphasis on designing assays that detect mutations with great efficiency (Vogel *et al.*, 1999; Casciano *et al.*, 1999; Lambert *et al.*, 2005; Dobrovolsky *et al.*, 2010). Nevertheless, there remains a gradation in which an increase in relevance for human risk entails more elaborate and costly tests (Table 9-2). The most expensive mammalian tests are typically reserved for agents of special importance in basic research or risk assessment, whereas the simpler assays can be applied more broadly.

Cytogenetic assays differ in design from typical gene mutation assays because of their reliance on cytological rather than genetic methods. The goal in cytogenetic methods is the unequivocal visual recognition of cells that have experienced genetic damage. The alterations measured include chromosome aberrations (Preston *et al.*, 1981; Ishidate *et al.*, 1988; Corvi *et al.*, 2008), micronuclei (Hayashi *et al.*, 2007; Corvi *et al.*, 2008; Fenech *et al.*, 2011a,b), SCEs (Tucker *et al.*, 1993a; Wilson and Thompson, 2007), and changes in chromosome number (Aardema *et al.*, 1998; Paccierotti and Sgura, 2008). The latter include ploidy changes (eg, polyploid cells) and aneuploidy, in which one or a few chromosomes have been gained (ie, hyperploidy) or lost (ie, hypoploidy) relative to the normal chromosome number. Aneuploidy is of great interest because of its implications for human health, but assays for aneuploidy are not yet as refined or systematically applied as those for other classes of chromosomal alterations.

In all mutagenicity testing, one must be aware of possible sources of error. Factors to consider in the application of mutagenicity assays are the choice of suitable organisms and growth conditions, appropriate monitoring of genotypes and phenotypes, effective experimental design and treatment conditions, inclusion of proper positive and negative controls, and sound methods of data analysis. The articles cited in Table 9-2 discuss these aspects of genetic toxicology testing.

Many compounds that are not themselves mutagenic or carcinogenic can be activated into mutagens and carcinogens by metabolism (Guenngerich, 2001; Malling, 2004). Such compounds are called promutagens and procarcinogens. Because microorganisms and mammalian cell cultures lack many of the metabolic capabilities of intact mammals, provision must be made for metabolic activation in order to detect promutagens in many genetic assays. Incorporating an *in vitro* metabolic activation system derived from a mammalian tissue homogenate is the most common means of adding metabolic activation to microbial or cell culture assays (Malling and Frantz,

1973; Ames *et al.*, 1975; Clements, 2000; Malling, 2004). For example, the promutagens dimethylnitrosamine and benzo[*a*]pyrene are not themselves mutagenic in bacteria, but they are mutagenic in bacterial assays if the bacteria are treated with the promutagen in the presence of a homogenate from mammalian liver.

The most widely used metabolic activation system in microbial and cell culture assays is a postmitochondrial supernatant from a rat liver homogenate, along with appropriate buffers and cofactors (Maron and Ames, 1983; Kirkland *et al.*, 1990). The standard liver metabolic activation system is called an S9 mixture, designating a supernatant from centrifugation at 9000*g* (Malling and Frantz, 1973; Maron and Ames, 1983). Most of the short-term assays in Table 9-2 require exogenous metabolic activation to detect promutagens. Exceptions are assays in intact mammals and a few simpler assays that have a high level of endogenous cytochrome P450 metabolism, such as the detection of UDS or DNA strand breakage in cultured hepatocytes (Madle *et al.*, 1994; Gealy *et al.*, 2007).

Rat liver S9 provides a broad assemblage of metabolic reactions, but they are not necessarily the same as those of hepatic metabolism in an intact rat. Metabolic activation systems based on homogenates from mice, guinea pigs, hamsters, or monkeys and preparations from organs other than liver have found some use in mutagenicity testing (Mortelmans and Zeiger, 2000). In some cases, these systems detect mutagenicity more efficiently than rat liver S9. However, like a homogenate from rat liver, these systems may differ from the species or organs of their origin. Therefore, alternative metabolic activation systems tend to be more useful if chosen for mechanistic reasons rather than simply testing another species or organ. Such systems include the use of intact hepatocytes (Madle *et al.*, 1994; Storer *et al.*, 1996; Gealy *et al.*, 2007) to preserve the cellular compartmentalization of reactions; an *in vitro* system that can carry out the reduction reactions needed to detect the activity of substances whose mutagenicity requires reductive metabolism, such as some azo compounds (Mortelmans and Zeiger, 2000; Seifried *et al.*, 2006); and the use of mammalian cells or bacteria engineered to express foreign genes that encode enzymes of metabolic activation (Sawada and Kamataki, 1998; Crespi and Miller, 1999; Josephy, 2000, 2002; Oda *et al.*, 2009).

Besides metabolic activation, some chemicals are subject to photochemical activation. The genotoxicity of such chemicals depends on the chemical being irradiated with ultraviolet or visible light. Many of the assays listed in Table 9-2, including gene-mutation assays in bacteria and cultured mammalian cells, cytogenetic assays, and the comet assay, have been adapted so that they can measure photogenotoxic effects (Brendler-Schwaab *et al.*, 2004; Lynch *et al.*, 2011).

Genes encoding enzymes of xenobiotic metabolism have been incorporated by recombinant DNA technology into microorganisms or cell cultures to expand their capacity for metabolic activation. The genes incorporated into bacteria may be derived from other bacteria or from humans (Josephy, 2002; Oda *et al.*, 2009). For example, bacterial genes that cause overexpression of N-acetyltransferase enhance the sensitivity of the bacteria to the mutagenicity of aromatic amines or nitroarenes (Josephy, 2002). The expression of human cytochrome P450 enzymes in *Salmonella* tester strains from the Ames assay (Josephy 2002; Yamazaki *et al.*, 2004), a *Salmonella* SOS-induction assay (Oda *et al.*, 2009), or *E. coli* strains of the *lacZ* reversion assay (Josephy, 2000) permits the activation of such promutagens as 2-aminoanthracene and 2-aminofluorene without an S9 mixture. Mammalian cell lines have also been genetically engineered to express human Phase-I and Phase-II enzymes, including those catalyzing reactions of metabolic activation (Sawada and Kamataki, 1998). Many cell lines

stably expressing a single form of P450 have been established. Mutagenesis can be measured through such endpoints as *HPRT* mutations and cytogenetic alterations, and the cells are well suited to analyzing the contribution of different enzymes to the activation of promutagens (Crespi and Miller, 1999).

Metabolic activation is so central to genetic toxicology that all mutagenicity testing programs must provide for it in the choice of assays and procedures. Despite their usefulness, *in vitro* metabolic activation systems, however well refined, cannot mimic mammalian metabolism perfectly. There are differences among tissues in reactions that activate or inactivate foreign compounds, and organisms of the normal flora of the gut can contribute to metabolism in intact mammals. Agents that induce enzyme systems or otherwise alter the physiological state can also modify the metabolism of toxicants, and the balance between activation and detoxication reactions *in vitro* may differ from that *in vivo*.

Structural Alerts and In Silico Assays

The first indication that a chemical is a mutagen often lies in chemical structure. Potential electrophilic sites in a molecule serve as an alert to possible mutagenicity and carcinogenicity because such sites confer reactivity with nucleophilic sites in DNA (Tennant and Ashby, 1991). Structural alerts in combination with critical interpretation are a valuable adjunct to mutagenicity testing (Tennant and Ashby, 1991; Ashby and Paton, 1993). Attempts to formalize the structural prediction through automated computer programs have not yet led to an ability to predict mutagenicity and carcinogenicity of new chemicals with great accuracy (Snyder *et al.*, 2004), but promising developmental work on such systems continues (Votano *et al.*, 2004; Snyder and Smith, 2005).

Computer-based systems for predicting genotoxicity based on chemical properties are sometimes called *in silico* assays. These assays include computational and structural programs (Knudsen *et al.*, 2011; Snyder and Smith, 2005; Snyder, 2009; Mahadevan *et al.*, 2011) and the modeling of quantitative structure–activity relationships (Votano *et al.*, 2004; Snyder and Smith, 2005; Mahadevan *et al.*, 2011). Although there is much skepticism that such approaches can replace biological testing, they hold promise of improving the efficiency of testing strategies and reducing current levels of animal use (Guha, 2011).

DNA Damage and Repair Assays

Some assays measure DNA damage itself, rather than mutational consequences of DNA damage. They may do so directly, through such indicators as chemical adducts or strand breaks in DNA, or indirectly, through the measurement of biological repair processes. Adducts in DNA are detected by ³²P-postlabeling, high-performance liquid chromatography (HPLC), fluorescence-based methods, mass spectrometry, immunological methods using antibodies against specific adducts, isotope-labeled DNA binding, and electrochemical detection (Phillips *et al.*, 2000; Farmer and Singh, 2008; Himmelstein *et al.*, 2009). The ³²P-postlabeling method is highly versatile, in that it is sensitive and can be applied to diverse mutagens, but it may fall short of other methods for quantitative accuracy (Farmer and Singh, 2008). Through a combination of methods, many classes of adducts, including those of such environmentally widespread compounds as polynuclear aromatic hydrocarbons, can be detected. The measurement of adducts after human chemical exposures has proven useful in human monitoring, molecular dosimetry, and risk assessment (Phillips *et al.*, 2000; Farmer and Singh, 2008; Himmelstein *et al.*, 2009). Adducts in somatic cells are relevant to carcinogenesis

(Himmelstein *et al.*, 2009), whereas those in reproductive cells permit molecular dosimetry for germ cell mutagenesis (Olsen *et al.*, 2010; 2011; Verhofsrad *et al.*, 2011).

DNA strand breakage can be measured by alkaline elution (Storer *et al.*, 1996; Gealy *et al.*, 2007) and electrophoretic methods. Single-cell gel electrophoresis, also called the comet assay, is a widely used, rapid method of measuring DNA damage (Fairbairn *et al.*, 1995; Singh, 2000; Tice *et al.*, 2000; Collins, 2004; Olive, 2009). In this assay cells are incorporated into agarose on slides, lysed so as to liberate their DNA, and subjected to electrophoresis. The DNA is stained with a fluorescent dye for observation and image analysis. Because broken DNA fragments migrate more quickly than larger pieces of DNA, a blur of fragments (a “comet”) is observed when the DNA is extensively damaged. The extent of DNA damage can be estimated from the length and other attributes of the comet tail (Collins, 2004). Variations in the procedure permit the general detection of DNA strand breakage under alkaline conditions (Fairbairn *et al.*, 1995; Singh, 2000; Tice *et al.*, 2000) or the preferential detection of double-strand breaks under neutral conditions (Fairbairn *et al.*, 1995; Olive, 2009). A recent development is the combination of the comet assay with FISH to detect damage in specific regions of the genome (Glei *et al.*, 2009; Shaposhnikov *et al.*, 2009). Although the comet assay is relatively new, it has proven to be a sensitive indicator of DNA damage with broad applicability. It has been used most commonly with human lymphocytes (Fairbairn *et al.*, 1995; Singh, 2000; Collins, 2004) and other mammalian cells (Tice *et al.*, 2000), but it can be adapted to diverse species, including plants, worms, mollusks, fish, and amphibians (Cotelle and Féraud, 1999; Lee and Steinert, 2003; Jha, 2004). This adaptability makes it well suited to use in environmental genetic toxicology. The applicability of the comet assay and other DNA damage assays to rodent testes (Bentley *et al.*, 1994; Speit *et al.*, 2009) makes these methods helpful in interpreting risks to germ cells.

The occurrence of DNA repair can serve as an easily measured indicator of DNA damage. Repair assays have been developed in microorganisms, cultured mammalian cells, and intact mammals (Table 9-2). Greater toxicity of a chemical in DNA-repair-deficient strains than in their repair-proficient counterparts (eg, *rec⁺* and *rec⁻* in *Bacillus subtilis*) can serve as an indicator of DNA damage in bacteria (Takigami *et al.*, 2002). Bacterial repair assays find occasional application but are used less commonly today than historically. The measurement of UDS, which is a measure of excision repair, is a mammalian DNA repair assay. The occurrence of UDS indicates that DNA has been damaged (Madle *et al.*, 1994). The absence of UDS, however, does not provide evidence that DNA has not been damaged because some classes of damage are not readily excised, and some excisable damage may not be detected as a consequence of assay insensitivity (Kirkland and Speit, 2008). Despite these limitations, UDS assays continue to find some use because of their applicability to cultured hepatocytes with endogenous cytochrome P450 enzyme activities and to tissues of intact animals, including hepatocytes (Madle *et al.*, 1994) and germinal tissue (Bentley *et al.*, 1994; Sotomayor and Segal, 2000).

Besides specific DNA repair processes, the induction of general responses to genotoxic stress has been used as an indicator of genetic damage. The induction of SOS functions, indicated by phage induction or by colorimetry, can serve as an indicator of genetic damage in bacteria (Quillardet and Hofnung, 1993; Yasunaga *et al.*, 2004; Oda *et al.*, 2009). The GADD45a-GFP assay, also called “Green Screen,” detects genotoxic stress in human lymphoblastoid TK6 cells (Hastwell *et al.*, 2009). The stress response is detected by a green-fluorescent protein reporter in the genetic construct, and the induction of fluorescence has been observed with

mutagens, clastogens, and aneugens (Hastwell *et al.*, 2009). The assay can be conducted with S9 metabolic activation and lends itself to automated detection by flow cytometry (Jagger *et al.*, 2009).

Gene Mutations in Prokaryotes

The most common means of detecting mutations in microorganisms is selecting for reversion in strains that have a specific nutritional requirement differing from wild type members of the species; such strains are called auxotrophs. For example, the widely used assay developed by Bruce Ames and his colleagues is based on measuring reversion in several histidine auxotrophs in *Salmonella enterica* serovar Typhimurium, commonly called *S typhimurium* (Ames *et al.*, 1975).

In the Ames assay one measures the frequency of histidine-independent bacteria that arise in a histidine-requiring strain in the presence or absence of the chemical being tested. Auxotrophic bacteria are treated with the chemical of interest by one of several procedures (eg, the standard plate-incorporation assay) and plated on medium that is deficient in histidine (Ames *et al.*, 1975; Maron and Ames, 1983; Mortelmans and Zeiger, 2000). The assay is conducted using genetically different strains so that reversion by base pair substitutions and frameshift mutations in several DNA sequence contexts can be detected and distinguished. Because *Salmonella* does not metabolize promutagens in the same way as mammalian tissues, the assay is generally performed in the presence and absence of a rat liver S9 metabolic activation system. Hence, the Ames assay is also called the *Salmonella*/microsome assay.

The principal strains of the Ames test and their characteristics are summarized in Table 9-3. In addition to the histidine alleles that provide the target for measuring mutagenesis, the Ames tester strains contain other genes and plasmids that enhance the assay. Part I of the table gives genotypes, and Part II explains the rationale for including specific genetic characteristics in the strains. Part III summarizes the principal DNA target in each strain and the mechanisms of reversion. Taken together, the Ames strains detect a broad array of mutations, and they complement one another. For example, strains TA102 and TA104, which are sensitive to agents that cause oxidative damage in DNA, detect the A:T → G:C base pair substitutions that are not detected by *hisG46* strains (Mortelmans and Zeiger, 2000). TA102 also detects agents that cause DNA cross-links because it has an intact excision repair system whereas the other common tester strains do not.

The most common version of the Ames assay is the plate-incorporation test (Ames *et al.*, 1975; Maron and Ames, 1983; Mortelmans and Zeiger, 2000). In this procedure, the bacterial tester strain, the test compound (or solvent control), and the S9 metabolic activation system (or buffer for samples without S9) are added to 2 mL of molten agar containing biotin and a trace of histidine to allow a few cell divisions, mixed, and immediately poured onto the surface of a petri dish selective for histidine-independent revertants. For general testing it is recommended that at least three plates per dose and five doses be used with and without S9, along with appropriate concurrent positive and negative controls (Mortelmans and Zeiger, 2000). Variations on the standard plate-incorporation assay confer advantages for some applications. These include a preincubation assay that facilitates the detection of unstable compounds and short-lived metabolites, a desiccator assay for testing volatile chemicals and gases, a microsuspension assay for working with small quantities of test agent, assays incorporating reductive metabolism rather than the conventional S9 system, and assays under hypoxic conditions (Mortelmans and Zeiger, 2000).

Although simplicity is a great merit of microbial assays, it can also be deceptive. Even assays that are simple in design and application can be performed incorrectly. For example, in the Ames assay one may see very small colonies in the petri dishes at highly toxic doses (Maron and Ames, 1983; Kirkland *et al.*, 1990; Mortelmans and Zeiger, 2000). Counting such colonies as revertants would be an error because they may actually be nonrevertant survivors that grew on the low concentration of histidine in the plates. Were there millions of survivors, the amount of histidine would have been insufficient to allow any of them (except real revertants) to form colonies. This artifact is easily avoided by checking that there is a faint lawn of bacterial growth in the plates; one can also confirm that colonies are revertants by streaking them on medium without histidine to be sure that they grow in its absence. Such pitfalls exist in all mutagenicity tests. Therefore, anyone performing mutagenicity tests must have detailed familiarity with the laboratory application and literature of the assay and be observant about the responsiveness of the assay.

Although information from the Ames assay has become a standard in genetic toxicology testing, equivalent information can be obtained from other bacterial assays. Like the Ames assay, the WP2 tryptophan reversion assay in *E coli* (Kirkland *et al.*, 1990; Mortelmans and Riccio, 2000) incorporates genetic features that enhance assay sensitivity, can accommodate S9 metabolic activation, and performs well in many laboratories. Mutations are detected by selecting for reversion of a *trpE* allele from Trp⁻ to Trp⁺. Its responsiveness to mutagens most closely resembles TA102 among the Ames strains (Mortelmans and Riccio, 2000).

Bacterial reversion assays are commonly used for testing purposes, but they also provide information on molecular mechanisms of mutagenesis. The broader understanding of mutational mechanisms that comes from refined genetic assays and molecular analysis of mutations can contribute to the interpretation of mutational hazards. The primary reversion mechanisms of the Ames strains, summarized in Table 9-3, were initially determined by genetic and biochemical means (Maron and Ames, 1983). An ingenious method called allele-specific colony hybridization greatly facilitated the molecular analysis of revertants in the Ames assay (Koch *et al.*, 1994), and many spontaneous and induced revertants have been cloned or amplified by the polymerase chain reaction (PCR) and sequenced (Levine *et al.*, 1994; DeMarini, 2000).

Part III of Table 9-3 is by necessity a simplification with respect both to targets and mechanisms of reversion of the Ames strains. Some mutations that bring about reversion to histidine independence fall outside the primary target, and the full target has been found to be as much as 76 base pairs in *hisD3052* (DeMarini *et al.*, 1998). Other revertants can arise by suppressor mutations in other genes. It has been shown that *hisG46*, *hisG428*, *hisC3076*, *hisD6610*, and *hisD3052* all revert by multiple mechanisms and that the spectrum of classes of revertants may vary depending on the mutagen, experimental conditions, and other elements of the genotype (Cebula and Koch, 1990; Prival and Cebula, 1992; DeMarini *et al.*, 1998; Mortelmans and Zeiger, 2000).

The development of *Salmonella* strains that are highly specific with respect to mechanisms of reversion has made the identification of particular base pair substitutions more straightforward. These strains (TA7001–TA7006) each revert from *his*⁻ to *his*⁺ by a single kind of mutation (eg, G:C to T:A), and collectively they permit the specific detection of all six possible base pair substitutions (Gee *et al.*, 1994; Mortelmans and Zeiger, 2000; Kamber *et al.*, 2009). The assay is usually conducted using a fluctuation test in 24-well plates, rather than the plate-incorporation or preincubation method. The ability to discern mutagens and nonmutagens is comparable to the standard Ames assay (Kamber *et al.*, 2009).

Table 9-3

The Ames Assay: Tester Strains and Their Characteristics

I. STANDARD TESTER STRAINS OF <i>SALMONELLA TYPHIMURIUM</i>			
STRAIN	TARGET ALLELE	CHROMOSOMAL GENOTYPE	PLASMIDS
TA1535	<i>hisG46</i>	<i>hisG46 rfa ΔuvrB</i>	None
TA100	<i>hisG46</i>	<i>hisG46 rfa ΔuvrB</i>	pKM101 (<i>mucAB Ap^r</i>)
TA1538	<i>hisD3052</i>	<i>hisD3052 rfa ΔuvrB</i>	None
TA98	<i>hisD3052</i>	<i>hisD3052 rfa ΔuvrB</i>	pKM101 (<i>mucAB Ap^r</i>)
TA1537	<i>hisC3076</i>	<i>hisC3076 rfa ΔuvrB</i>	None
TA97	<i>hisD6610</i>	<i>hisD6610 hisO1242 rf ΔuvrB</i>	pKM101 (<i>mucAB Ap^r</i>)
TA102	<i>hisG428</i>	<i>hisΔ(G)8476 rfa</i>	pKM101 (<i>mucAB Ap^r</i>); pAQ1 (<i>hisG428 Tc^r</i>)
TA104	<i>hisG428</i>	<i>hisG428 rfa ΔuvrB</i>	pKM101 (<i>mucAB Ap^r</i>)
II. GENETIC CHARACTERISTICS OF THE AMES TESTER STRAINS			
CHARACTERISTIC	RATIONALE FOR INCLUSION IN THE TESTER STRAIN		
<i>rfa</i>	Alters the lipopolysaccharide wall, enhancing permeability to mutagens.		
<i>ΔuvrB</i>	Deletes the excision repair system, increasing sensitivity to many mutagens; retention of excision in TA102 permits the detection of DNA cross-linking agents.		
<i>mucAB</i>	Enhances sensitivity to some mutagens whose activity depends on the SOS system.		
<i>Ap^r</i>	Permits selection for the presence of pKM101 by ampicillin resistance.		
<i>hisO1242</i>	Affects regulation of histidine genes, enhancing revertibility of <i>hisD6610</i> in TA97.		
<i>His Δ(G)8476</i>	Eliminates the chromosomal <i>hisG</i> gene, allowing detection of the reversion of <i>hisG428</i> on pAQ1 in TA102.		
<i>Tc^r</i>	Permits selection for the presence of pAQ1 in TA102 by tetracycline resistance.		
III. MECHANISMS OF REVERSION DETECTED BY THE AMES TESTER STRAINS			
STRAIN	PRIMARY TARGET*	MUTATIONS DETECTED	
TA1535, TA100	GGG/CCC	Base-pair substitutions, principally those beginning at G:C base pairs (G:C→A:T; G:C→T:A; G:C→C:G). These strains also detect A:T→C:G but not A:T→G:C.	
TA1538, TA98	CGCGCGCG/GCGCGCGC	Frameshift mutations, especially -2 frameshifts (-GC or -CG), +1 frameshifts, other small deletions, and some complex mutations.	
TA1537	GGGGG/CCCCC	Frameshift mutations, mainly -1 (-G or -C; less frequently -T), but also some +CG frameshifts.	
TA97	GGGGGG/CCCCCC	Frameshift mutations, combining the specificity of TA1537 at the primary target and with some characteristics of TA98.	
TA102, TA104	TAA/ATT	Base-pair substitutions, principally those beginning at A:T base pairs (A:T→G:C; A:T→T:A; A:T→C:G), but also G:C→T:A and G:C→A:T.	

*The sequences before and after the backslash represent the 2 complementary strands of DNA.

Specific reversion assays are also available in *E. coli*. A versatile system based on reversion of *lacZ* mutations in *E. coli* permits the specific detection of all six possible base pair substitutions (Cupples and Miller, 1989; Josephy, 2000) and frameshift mutations for which one or two bases have been added or deleted in various sequence contexts (Cupples *et al.*, 1990; Josephy, 2000; Hoffmann *et al.*, 2003). The versatility of the *lacZ* assay has been expanded through the introduction of useful characteristics into the strains parallel to those incorporated into the Ames strains. Among the features added to the *lacZ* assay are DNA repair deficiencies, permeability alterations, plasmid-enhanced mutagenesis, and enzymes of mutagen metabolism (Josephy, 2000).

Bacterial forward mutation assays, such as selections for resistance to arabinose or to purine or pyrimidine analogs in *Salmonella* (Jurado *et al.*, 1994; Vlasakova *et al.*, 2005), are also used in research and testing, although less extensively than reversion assays. A versatile forward mutation assay that has contributed greatly to an understanding of mechanisms of mutagenesis is the *lacI* system in *E. coli* (Calos and Miller, 1981; Halliday and Glickman, 1991). Mutations in the *lacI* gene, which encodes the repressor of the lactose operon, are easily identified by phenotype, cloned or amplified by PCR, and sequenced. The *lacI* gene is widely used as a target for mutagenesis both in *E. coli* and in transgenic mice, and thousands of *lacI* mutants have been sequenced.

Genetic Alterations in Nonmammalian Eukaryotes

Gene Mutations and Chromosome Aberrations Many early studies of mutagenesis used yeasts, mycelial fungi, plants, and insects as experimental organisms. Even though well-characterized genetic systems permit the analysis of a diverse array of genetic alterations in these organisms (Table 9-2), they have been largely supplanted in genetic toxicology by bacterial and mammalian systems. Exceptions are to be found where the assays in nonmammalian eukaryotes permit the study of genetic endpoints that are not readily analyzed in mammals or where the organism has special attributes that fit a particular application.

The fruit fly, *Drosophila*, has long occupied a prominent place in genetic research. In fact, the first unequivocal evidence of chemical mutagenesis was obtained in Scotland in 1941 when Charlotte Auerbach and J.M. Robson demonstrated that mustard gas is mutagenic in *Drosophila*. *Drosophila* continues to be used in modern mutation research (Potter *et al.*, 2000) but its role in genetic toxicology is now more limited. The *Drosophila* assay of greatest historical importance is the sex-linked recessive lethal (SLRL) test. A strength of the SLRL test is that it permits the detection of recessive lethal mutations at 600 to 800 different loci on the X chromosome by screening for the presence or absence of wild type males in the offspring of specifically designed crosses (Mason *et al.*, 1987; Vogel *et al.*, 1999). The genetic alterations include gene mutations and small deletions. The spontaneous frequency of SLRL is about 0.2%, and a significant increase over this frequency in the lineages derived from treated males indicates mutagenesis. Although it requires screening large numbers of fruit fly vials, the SLRL test yields information about mutagenesis in germ cells, which is lacking in all microbial and cell culture systems. However, means of exposure, measurement of doses, metabolism, and gametogenesis in insects differ from those in mammalian toxicology, thereby introducing doubt about the relevance of *Drosophila* assays to human genetic risk. *Drosophila* assays are also available for studying the induction of chromosome abnormalities in germ cells, specifically heritable translocations (Mason *et al.*, 1987; Vogel *et al.*, 1999).

Genetic and cytogenetic assays in plants (Ma *et al.*, 2005; Grant and Owens, 2006; Misík *et al.*, 2011) also occupy a more restricted niche in modern genetic toxicology than they did years ago. However, plant assays continue to find use in special applications, such as in situ monitoring for mutagens and exploration of the metabolism of promutagens by agricultural plants. In situ monitoring entails looking for evidence of mutagenesis in organisms that are grown in the environment of interest. Natural plant populations can also be examined for evidence of genetic damage, but doing so requires utmost precaution when characterizing the environments and defining appropriate control populations.

Mitotic Recombination Assays in nonmammalian eukaryotes continue to be important in the study of induced recombination. Recombinogenic effects in yeast have long been used as a general indicator of genetic damage (Zimmermann *et al.*, 1984), and interest in the induction of recombination has increased as recombinational events have been implicated in the etiology of cancer (Sengstag, 1994; Reliene *et al.*, 2007). LOH is central to the expression of the mutant alleles of tumor-suppressor genes, and mitotic recombination is a major mechanism of LOH. Widely used assays for recombinogens detect mitotic crossing over and mitotic gene conversion in the yeast *Saccharomyces cerevisiae* (Zimmermann, 1992), and hundreds of chemicals have been tested for recombinogenic effects in straightforward yeast assays (Zimmermann *et al.*, 1984). In yeast

strain D7, for example, mitotic crossing over involving the *ade2* locus is detected on the basis of pink and red colony color, mitotic gene conversion at the *trp5* locus by selection for growth without tryptophan, and gene mutations by reversion of the *ilv1-92* allele (Zimmermann, 1992; Freeman and Hoffmann, 2007). Newer yeast assays have been constructed to discern whether LOH has occurred by mitotic recombination or chromosome loss (Daigaku *et al.*, 2004; Nunoshiha *et al.*, 2007). Strategies have also been devised to detect recombinogenic effects in human lymphocytes (Turner *et al.*, 2003), other mammalian cells, mice, plants, and mycelial fungi (Hoffmann, 1994; Reliene *et al.*, 2007). At least 350 chemicals have been evaluated in *Drosophila* somatic cell assays in which recombinogenic effects are detected by examining wings or eyes for regions in which recessive alleles are expressed in heterozygotes (Vogel *et al.*, 1999; Vogel and Nivard, 2000).

Gene Mutations in Mammals

Gene Mutations In Vitro Mutagenicity assays in cultured mammalian cells have some of the same advantages as microbial assays with respect to speed and cost, and they use similar approaches. The most widely used assays for gene mutations in mammalian cells detect forward mutations that confer resistance to a toxic chemical. For example, mutations in the gene encoding hypoxanthine-guanine phosphoribosyltransferase (HPRT enzyme; *HPRT* gene) confer resistance to the purine analogue 6-thioguanine (Li *et al.*, 1988; Parry *et al.*, 2005), and thymidine kinase mutations (TK enzyme; *TK* gene) confer resistance to the pyrimidine analogue trifluorothymidine (Clements, 2000; Wang *et al.*, 2009). HPRT and TK mutations may therefore be detected by attempting to grow cells in the presence of purine analogues and pyrimidine analogues, respectively. For historical reasons, HPRT assays have most commonly been conducted in Chinese hamster cells or human cells, whereas TK assays have used mouse lymphoma cells or human cells. The mouse lymphoma assay, long used for detecting gene mutations, is now also used to detect other endpoints, including recombination, deletion, and aneuploidy (Wang *et al.*, 2009). Forward-mutation assays typically respond to diverse mechanisms of mutagenesis, but there are exceptions such as resistance to ouabain, which only occurs by a specific alteration (DeMarini *et al.*, 1989). Assays that do not detect various kinds of mutations are not useful for general mutagenicity testing. Genetic or molecular evidence that an assay is responsive to diverse mechanisms of mutagenesis is essential.

Instead of using selective media, flow cytometry can be used to detect gene mutations by immunological methods in mammalian cell cultures and intact animals. An in vitro assay for CD59 mutations is performed in CHO-human hybrid A_L cells (Zhou *et al.*, 2006). A_L cells contain a single human chromosome 11 along with the Chinese hamster chromosome complement of the Chinese hamster ovary (CHO) cells. CD59 is a cell-surface protein encoded by a gene on the human chromosome. Fluorescent anti-CD59 antibody is used to quantify CD59 cells by flow cytometry. Besides CD59 itself, mutations in other CD genes on chromosome 11 and in their glycosylphosphatidylinositol (GPI) anchor can be detected in the assay (Ross *et al.*, 2007). An assay for mutations in *Pig-a*, the GPI anchor gene, is discussed with in vivo assays.

Gene Mutations In Vivo In vivo assays involve treating intact animals and analyzing appropriate tissues for genetic effects. The choice of suitable doses, treatment procedures, controls, and sample sizes is critical in the conduct of in vivo tests. Mutations may be detected either in somatic cells or in germ cells. The latter are of special interest with respect to risk for future generations.

The mouse spot test is a traditional genetic assay for gene mutations in somatic cells (Styles and Penman, 1985; Lambert *et al.*, 2005). Visible spots of altered phenotype in mice heterozygous for coat-colored genes indicate mutations in the progenitor cells of the altered regions. Although straightforward in design, the spot test is less used today than other somatic cell assays or than its germ cell counterpart, the mouse specific-locus test.

Cells that are amenable to positive selection for mutants when collected from intact animals form the basis for efficient *in vivo* mutation-detection assays analogous to those in mammalian cell cultures. Lymphocytes with mutations in the *HPRT* gene are readily detected by selection for resistance to 6-thioguanine. The *hprt* assay in mice, rats, and monkeys (Casciano *et al.*, 1999) is of special interest because it permits comparisons to the measurement of *HPRT* mutations in humans in mutational monitoring (Cole and Skopek, 1994; Albertini and Hayes, 1997; Albertini, 2001).

The *Pig-a* assay is a newer assay that has versions suitable for human monitoring and laboratory studies. The assay detects mutations that block GPI synthesis (Dobrovolsky *et al.*, 2010). *Pig-a* is a sex-linked gene whose gene product functions as an anchor for cell-surface proteins. Mutations in *Pig-a* can be detected in red blood cells from rats, mice, monkeys, and humans by means of fluorescent antibodies against GPI-anchored cell-surface proteins, such as CD59. Using antibodies to more than one GPI-linked marker has been suggested as a means of making the assay specific to *Pig-a* rather than also detecting mutants for a particular cell-surface protein. Frequencies can be measured by clonal growth of *Pig-a* cells using proaerolysin (ProAER) selection or by flow cytometry (Dobrovolsky *et al.*, 2010; Miura *et al.*, 2011; Dobo *et al.*, 2011). The fact that the same assay can be performed in several species makes this a promising assay for comparisons of human monitoring and controlled exposures in laboratory animals.

Besides determining whether agents are mutagenic, mutation assays provide information on mechanisms of mutagenesis that contributes to an understanding of mutational hazards. Base pair substitutions and large deletions, which may be indistinguishable on the basis of phenotype, can be differentiated through the use of probes for the target gene and Southern blotting, in that base substitutions are too subtle to be detectable on the blots, whereas gross structural alterations are visible (Cole and Skopek, 1994; Albertini and Hayes, 1997). Molecular analysis has been used to determine proportions of mutations ascribable to deletions and other structural alterations in several assays, including the specific-locus test for germ cell mutations in mice (Favor, 1999) and the human *HPRT* assay (Cole and Skopek, 1994). Gene mutations have been characterized at the molecular level by DNA sequence analysis both in transgenic rodents (Lambert *et al.*, 2005; Singer *et al.*, 2006) and in endogenous mammalian genes (Cariello and Skopek, 1993). Many *HPRT* mutations from human cells *in vitro* and *in vivo* have been analyzed at the molecular level and classified with respect to base pair substitutions, frameshifts, small deletions, large deletions, and other alterations (Cole and Skopek, 1994).

Transgenic Assays Transgenic animals are products of DNA technology in which the animal contains foreign DNA sequences that have been added to the genome. The foreign DNA is represented in all the somatic cells of the animal and is transmitted in the germ line to progeny. Mutagenicity assays in transgenic animals combine *in vivo* metabolic activation and pharmacodynamics with simple microbial detection systems, and they permit the analysis of mutations induced in diverse mammalian tissues (Lambert *et al.*, 2005; Sykes *et al.*, 2006; Valentine *et al.*, 2010).

The transgenic animals that have figured most heavily in genetic toxicology are rodents that carry *lac* genes from *E. coli*. The bacterial genes were introduced into mice or rats by injecting a vector carrying the genes into fertilized oocytes (Lambert *et al.*, 2005). The strains are commonly referred to by their commercial names—the “Big Blue mouse” and “Big Blue rat,” which use *lacI* as a target for mutagenesis, and the “Muta Mouse,” which uses *lacZ* (Lambert *et al.*, 2005). After mutagenic treatment of the transgenic animals, the *lac* genes are recovered from the animal, packaged in phage λ , and transferred to *E. coli* for mutational analysis. Mutant plaques are identified on the basis of phenotype, and mutant frequencies can be calculated for different tissues of the treated animals. The *cII* locus may be used as a second target gene in both the *lacZ* and *lacI* transgenic assays (Swiger, 2001; Lambert *et al.*, 2005). Its use offers technical advantages as a small, easily sequenced target in which mutations are detected by positive selection, and it permits interesting comparisons both within and between assays.

A *lacZ* transgenic mouse that uses a plasmid-based system rather than a phage vector has the advantage that deletion mutants are more readily recovered than in the phage-based *lac* systems (Lambert *et al.*, 2005). Deletions may also be detected in the *gpt delta* mouse and rat using a phage vector system. These transgenic animals detect two kinds of genetic events in two targets—point mutations in *gpt* detected by resistance to 6-thioguanine and *spi* deletions that permit growth on P2 lysogens (Okada *et al.*, 1999; Lambert *et al.*, 2005). Other transgenic assays are under development and offer the prospect of expanding the versatility of such assays (Lambert *et al.*, 2005). These include pKZ1 mice in which inversions and deletions arising in various tissues by intrachromosomal recombination have been used to study effects of low doses of ionizing radiation (Sykes *et al.*, 2006) and an assay that detects both forward mutations and reversion in mice that carry the genome of phage Φ X174 (Valentine *et al.*, 2010).

Various mutagens, including alkylating agents, nitrosamines, procarbazine, cyclophosphamide, and polycyclic aromatic hydrocarbons have been studied in transgenic mouse assays, and mutant frequencies have been analyzed in such diverse tissues as liver, skin, spleen, kidney, bladder, small intestine, bone marrow, and testis (Lambert *et al.*, 2005). Mutation frequencies in transgenes in testes have been compared to results in standard germ cell mutagenesis assays (Singer *et al.*, 2006). Female germ cells are less amenable to study in transgenic assays because of the difficulty of collecting sufficient numbers of oocytes, but it has been suggested that granulosa cells from ovarian follicles may serve as a surrogate for the exposure of female germ cells to mutagens (Singer *et al.*, 2006). Mutant frequencies have been compared to the formation of adducts in various tissues and to the site specificity of carcinogenesis and DNA repair capacity (Lambert *et al.*, 2005). An important issue that remains to be resolved is the extent to which transgenes resemble endogenous genes. Although their mutational responses tend to be comparable (Lambert *et al.*, 2005), some differences have been noted (Burkhart and Malling, 1993; Lambert *et al.*, 2005), and questions have been raised about the relevance of mutations that might be recovered from dying or dead animal tissues (Burkhart and Malling, 1994). Therefore, transgenic animals offer promising models for the study of chemical mutagenesis, but they must be further characterized before their ultimate place in hazard assessment is clear.

Mammalian Cytogenetic Assays

Chromosome Aberrations Cytogenetic assays rely on the use of microscopy for the direct observation of the effects of interest. This approach differs sharply from the indirectness of traditional

Figure 9-4. Chromosome aberrations induced by x-rays in Chinese hamster ovary (CHO) cells. (A) A chromatid deletion (▶). (B) A chromatid exchange called a triradial (▶). (C) A small interstitial deletion (▶) that resulted from chromosome breakage. (D) A metaphase with more than one aberration: a centric ring plus an acentric fragment (▶) and a dicentric chromosome plus an acentric fragment (→).

genetic assays in which one observes a phenotype and reaches conclusions about genes. It is only through the addition of DNA sequencing that genetic assays can approach the directness of cytogenetic assays.

In conventional cytogenetics, metaphase analysis is used to detect chromosomal anomalies, especially unstable chromosome and chromatid aberrations. A key factor in the design of cytogenetic assays is obtaining appropriate cell populations for treatment and analysis (Preston *et al.*, 1981; Ishidate *et al.*, 1988; Kirkland *et al.*, 1990; Galloway *et al.*, 1994). Cells with a stable, well-defined karyotype, short generation time, low chromosome number, and large chromosomes are ideal for cytogenetic analysis. For this reason, Chinese hamster cells have been used widely in cytogenetic testing. Other cells are also suitable, and human cells, especially peripheral lymphocytes, have been used extensively. Cells should be treated during a sensitive period of the cell cycle (typically S), and aberrations should be analyzed at the first mitotic division after treatment so that the sensitivity of the assay is not reduced by unstable aberrations being lost during cell division. Examples of chromosome aberrations are shown in Fig. 9-4.

Cytogenetic assays require careful attention to growth conditions, controls, doses, treatment conditions, and time intervals between treatment and the sampling of cells for analysis (Preston *et al.*, 1981; Ishidate *et al.*, 1988; Kirkland *et al.*, 1990; Galloway *et al.*, 2011). Data collection is a critical part of cytogenetic analysis. It is essential that sufficient cells be analyzed because a negative result in a small sample is inconclusive. Results should be recorded for specific classes of aberrations, not just an overall index of aberrations per cell. The need for detailed data is all the more important because of nonuniformity in the classification of aberrations and disagreement on whether small achromatic (ie, unstained) gaps in chromosomes are true chromosomal aberrations. Gaps should be quantified but not pooled with other aberrations.

In interpreting results on the induction of chromosome aberrations in cell cultures, one must be alert to the possibility of artifacts associated with extreme assay conditions because aberrations

induced under such circumstances may not be a reflection of a chemical-specific genotoxicity (Scott *et al.*, 1991; Galloway, 2000; Galloway *et al.*, 2011). Questionable positive results have been found at highly cytotoxic doses (Galloway *et al.*, 2011), high osmolality, and pH extremes (Scott *et al.*, 1991). The possibility that metabolic activation systems may be genotoxic also warrants scrutiny (Scott *et al.*, 1991). Although excessively high doses may lead to artifactual positive responses, the failure to test to a sufficiently high dose also undermines the utility of a test. Therefore, testing should be extended to a dose at which there is some cytotoxicity, such as a reduction in a replicative index or the mitotic index (the proportion of cells in division). If the chemical is nontoxic, testing dosages should extend up to an arbitrary limit of dosage (Galloway *et al.*, 2011). By a consensus of cytogeneticists and genetic toxicologists, a limit of 10 mM or 5 mg/mL, whichever is lower, has been recommended (Galloway *et al.*, 2011). Some have argued that the limit should be lowered, perhaps to 1 mM, but no consensus could be reached on this point (Galloway *et al.*, 2011).

In vivo assays for chromosome aberrations involve treating intact animals and later collecting cells for cytogenetic analysis (Preston *et al.*, 1981; Kirkland *et al.*, 1990; Tice *et al.*, 1994). The main advantage of in vivo assays is that they include mammalian metabolism, DNA repair, and pharmacodynamics. The target is typically a tissue from which large numbers of dividing cells are easily prepared for analysis. Bone marrow from rats, mice, or Chinese hamsters is most commonly used. Peripheral lymphocytes are another suitable target when stimulated to divide with a mitogen such as phytohemagglutinin. Effective testing requires dosages and routes of administration that ensure adequate exposure of the target cells, proper intervals between treatment and collecting cells, and sufficient numbers of animals and cells analyzed (Preston *et al.*, 1981; Kirkland *et al.*, 1990; Tice *et al.*, 1994).

An important development in cytogenetic analysis is FISH, in which a nucleic acid probe is hybridized to complementary sequences in chromosomal DNA (Tucker *et al.*, 1993b, 2005; Paccierotti and Sgura, 2008). The probe is labeled with a fluorescent dye so that the chromosomal location to which it binds is visible by fluorescence microscopy. Composite probes have been developed from sequences unique to specific human chromosomes, giving a uniform fluorescent label over the entire chromosome. Slides prepared for standard metaphase analysis are suitable for FISH after they have undergone a simple denaturation procedure. The use of whole-chromosome probes is commonly called “chromosome painting” (Tucker *et al.*, 1993b; Speicher and Carter, 2005; Paccierotti and Sgura, 2008). Another significant advantage of FISH methods is that the probes can be used with interphase cells/chromosomes making any tissue potentially available for analysis (Vorsanova *et al.*, 2010). Examples of cells showing chromosome painting and reciprocal translocations are shown in Figs. 9-5 and 9-6.

Chromosome painting facilitates cytogenetic analysis because aberrations are easily detected by the number of fluorescent regions in a painted metaphase. For example, if chromosome 4 were painted with a probe while the other chromosomes were counter-stained in a different color, one would see only the two homologues of chromosome 4 in the color of the probe in a normal cell. However, if there were a translocation or a dicentric chromosome and fragment involving chromosome 4, one would see three areas of fluorescence—one normal chromosome 4 and the two pieces involved in the chromosome rearrangement. Aberrations are detected only in the painted portion of the genome, but this disadvantage can be offset by painting a few chromosomes simultaneously with probes of different colors (Tucker *et al.*, 1993b). FISH reduces the time and technical skill required to detect chromosome aberrations, and

Figure 9-5. Karyotype of human cell using FISH. To produce a FISH-based karyotype of the type depicted here, appropriate chromosome probe sets are developed for each chromosome pair such that by using computer colorization each has a specific color for analysis. (Reproduced with permission from Schrock E, et al. Multicolor spectral karyotyping of human chromosomes. *Science*. 1996 Jul 26;273(5274):494–497.)

it permits the scoring of stable aberrations, such as translocations and insertions, that are not readily detected in traditional metaphase analysis without special labeling techniques. Using FISH, some chromosomal analysis can even be conducted in interphase cells (Paccierotti and Sgura, 2008; Vorsanova *et al.*, 2010). Although FISH is not routinely used in genotoxicity testing, it is a valuable research tool for studying clastogens and is having a substantial impact in monitoring human populations for chromosomal damage.

Micronuclei Metaphase analysis is time consuming and requires considerable skill, so simpler cytogenetic assays have been developed, of which micronucleus assays have become especially important. Micronuclei are membrane-bound structures that contain chromosomal fragments, or sometimes whole chromosomes, that were not incorporated into a daughter nucleus at mitosis. Because micronuclei usually represent acentric chromosomal fragments, they are most commonly used as simple indicators of chromosomal damage. However, the ability to detect micronuclei containing whole chromosomes has led to their use for detecting aneuploidy as well. Micronucleus assays may be conducted in primary cultures of human lymphocytes (Fenech *et al.*, 2003; Corvi *et al.*, 2008; Fenech, 2008; Fenech *et al.*, 2011b), mammalian cell lines (Kirsch-Volders *et al.*, 2003; Corvi *et al.*, 2008), or mammals in vivo (Krishna and Hayashi, 2000; Hayashi *et al.*, 2007; Dertinger *et al.*, 2011).

Micronucleus assays in lymphocytes have been greatly improved by the cytokinesis-block technique in which cell division is inhibited with cytochalasin B, resulting in binucleate and multinucleate cells (Fenech *et al.*, 2003, 2011b; Kirsch-Volders *et al.*, 2003; Fenech, 2008). In the cytokinesis-block assay in human lymphocytes, nondividing (G_0) cells are treated with ionizing radiation or a radiomimetic chemical and then stimulated to divide with the mitogen phytohemagglutinin. Alternatively, the lymphocytes may be exposed to the mitogen first, so that the subsequent mutagenic treatment with radiation or chemicals includes the S period of the cell cycle. In either case, cytochalasin B is added for the last part of

Figure 9-6. Chromosome aberrations identified by FISH. Human breast cancer cell with aneuploidy for some chromosomes and with reciprocal translocations (identified by color switches along a chromosome).

the culture period, and micronuclei are counted only in binucleate cells so as to ensure that the cells have undergone a single nuclear division that is essential for micronucleus development. The assay thereby avoids confusion owing to differences in cellular proliferation kinetics.

Although first devised using primary lymphocytes (Fenech *et al.*, 2003; Fenech, 2008; Fenech, 2011b), the cytokinesis-block micronucleus assay has since been adapted for use in continuous cell cultures, including the Chinese hamster and mouse lymphoma cells that are widely used in other genotoxicity assays (Kirsch-Volders *et al.*, 2003; Corvi *et al.*, 2008). Micronucleus assays should be conducted in such a way that cellular proliferation is monitored along with the micronucleus frequency, and this is facilitated by the cytokinesis block. Reliable data have been obtained in cultured cells both with and without cytokinesis block, but scoring results only in binucleate cells after blockage of cytokinesis with cytochalasin B confers advantages with respect to the measurement of proliferation, recognizing whether an agent is cytostatic, and obtaining clear dose–response relationships (Kirsch-Volders *et al.*, 2003).

Although micronuclei resulting from chromosome breakage comprise the principal endpoint in the cytokinesis-block micronucleus assay, the method can also provide evidence of aneuploidy, chromosome rearrangements that form nucleoplasmic bridges, inhibition of cell division, necrosis, apoptosis, and excision-repairable lesions (Fenech *et al.*, 2003; Fenech, 2008; Fenech *et al.*, 2011b). Micronuclei in a binucleate human lymphocyte are shown in Fig. 9-7. A recent review of the International Human Micronucleus (HUMN) Project provides a comprehensive description of standardized protocols for micronucleus assays in human lymphocytes and buccal cells together with a review of associations between micronucleus data and disease outcomes (Fenech *et al.*, 2011a).

The in vivo micronucleus assay is often performed by counting micronuclei in immature (polychromatic) erythrocytes in the bone marrow of treated mice, but it may also be based on peripheral blood

Figure 9-7. *Micronucleus in a human lymphocyte.* The cytochalasin B method was used to inhibit cytokinesis that resulted in a binucleate nucleus. The micronucleus (arrow) resulted from failure of an acentric chromosome fragment or a whole chromosome being included in a daughter nucleus following cell division. (Figure courtesy of James Allen, Jill Barnes, and Barbara Collins.)

(Krishna and Hayashi, 2000; Hayashi *et al.*, 2007). Micronuclei remain in the cell when the nucleus is extruded in the maturation of erythroblasts. *In vivo* micronucleus assays are increasingly used in genotoxicity testing as a substitute for bone marrow metaphase chromosome analysis. Micronucleus assays have been developed for mammalian tissues other than bone marrow and blood, including skin, duodenum, colon, liver, lung, spleen, testes, bladder, buccal mucosal cells, stomach, vagina, and fetal tissues (Coffing *et al.*, 2011; Morita *et al.*, 2011). Although assays in bone marrow and blood are the mainstay of genotoxicity testing, the new assays are important for mechanistic studies and research on the site specificity of genetic damage and carcinogenesis.

Micronuclei are most commonly visualized through microscopy, but automated means of detecting micronuclei are being developed through the application of flow cytometry. Flow cytometric detection is effective in micronucleus assays in rodent bone marrow or blood (Dertinger *et al.*, 2011). It can also be used to detect micronuclei in Chinese hamster CHO cells, where altered flow cytometric parameters can reveal whether the micronuclei arose primarily by chromosome breakage or by aneuploidy (Bryce *et al.*, 2011).

Sister Chromatid Exchanges SCE, in which there has been an apparently reciprocal exchange of segments between the two chromatids of a chromosome, are visible cytologically through differential staining of chromatids. Fig. 9-8 shows SCE in human cells. Many mutagens induce SCE in cultured cells and in mammals *in vivo* (Tucker *et al.*, 1993a; Wilson and Thompson, 2007). Despite the convenience and responsiveness of SCE assays, data on SCE are less informative than data on chromosome aberrations. There is uncertainty about the underlying mechanisms by which SCEs are formed and how DNA damage or perturbations of DNA synthesis stimulate their formation (Preston, 1991). SCE assays are therefore best regarded as general indicators of mutagen exposure, analogous to DNA damage and repair assays, rather than measures of a mutagenic effect.

Aneuploidy Although assays for the induction of aneuploidy are not yet as refined as those for gene mutations and chromosome aberrations, they are being developed (Aardema *et al.*, 1998). The targets of aneugens are often components of the mitotic or meiotic apparatus, rather than DNA. Therefore, aneugens should not be expected to overlap strongly with mutagens and clastogens. For example, a chemical that interferes with the polymerization of tubulin and thereby disrupts the formation of a mitotic spindle is likely to show specificity as an aneugen. Assays for chemicals that induce aneuploidy should therefore encompass all the relevant cellular targets that are required for the proper functioning of the mitotic and meiotic process. Means of detecting aneuploidy include chromosome counting (Galloway and Ivett, 1986; Natarajan, 1993; Aardema *et al.*, 1998; Paccierotti and Sgura, 2008), the detection of micronuclei that contain kinetochores (Lynch and Parry, 1993; Natarajan, 1993; Aardema *et al.*, 1998; Fenech, 2008; Paccierotti

Figure 9-8. *Sister chromatid exchanges (SCEs) in human lymphocytes.* (A) SCE in untreated cell. (B) SCE in cell exposed to ethyl carbamate. The treatment results in a very large increase in the number of SCE. (Figure courtesy of James Allen and Barbara Collins.)

and Sgura, 2008), and the observation of abnormal spindles or spindle–chromosome associations in cells in which spindles and chromosomes have been differentially stained (Parry, 1998). FISH-based assays have also been developed for the assessment of aneuploidy in interphase somatic cells (Rupa *et al.*, 1997; Paccierotti and Sgura, 2008) and in sperm (Russo, 2000; Marchetti *et al.*, 2006, 2008).

A complication in chromosome counting is that a metaphase may lack chromosomes because they were lost during cell preparation for analysis, rather than having been absent from the living cell. To avoid this artifact, cytogeneticists generally use extra chromosomes (ie, hyperploidy) rather than missing chromosomes (ie, hypoploidy) as an indicator of aneuploidy in chromosome preparations from mammalian cell cultures (Galloway and Ivett, 1986; Aardema *et al.*, 1998) or mouse bone marrow (Adler, 1993). Techniques for counting chromosomes in intact cells may allow reliable measures of hypoploidy (Natarajan, 1993), but the detection of hyperploidy remains the norm in lieu of clear evidence that artifactual chromosome loss has been avoided. It has been suggested that counting polyploid cells, which is technically straightforward, may be an efficient way to detect aneuploids (Aardema *et al.*, 1998), but there is disagreement on the point (Parry, 1998).

Micronucleus assays can detect aneuploids as well as clastogens. Micronuclei that contain whole chromosomes tend to be somewhat larger than those containing chromosome fragments, but the two categories are not readily distinguished in typically stained preparations (Natarajan, 1993). However, one can infer that a micronucleus contains a whole chromosome if it is shown to contain a kinetochore or centromeric DNA. Aneuploidy may therefore be detected by means of antikinetochore antibodies with a fluorescent label or FISH with a probe for centromere-specific DNA (Lynch and Parry, 1993; Natarajan, 1993; Krishna and Hayashi, 2000; Fenech, 2008; Paccierotti and Sgura, 2008). Micronuclei containing kinetochores or centromeric DNA may be detected in cultured cells (Lynch and Parry, 1993; Aardema *et al.*, 1998; Fenech, 2008; Paccierotti and Sgura, 2008) and in mouse bone marrow *in vivo* (Adler, 1993; Krishna and Hayashi, 2000). Frequencies of micronuclei ascribable to aneuploidy and to clastogenic effects may therefore be determined concurrently by tabulating micronuclei with and without kinetochores.

Germ Cell Mutagenesis

Gene Mutations Germ cell mutagenesis assays are of special interest as indicators of genetic damage that can enter the gene pool and be transmitted through generations. Mammalian germ cell assays provide the best basis for assessing risks to human germ cells and therefore hold a central place in genetic toxicology despite their relative complexity and expense. The design of the test must compensate for the fact that mutations occur at low frequency, and even the simplest animal systems face the difficulty of their having a sufficiently large sample size. One can easily screen millions of bacteria or cultured cells by selection techniques, but screening large numbers of mice poses practical limitations. Therefore, a germ cell assay must offer a straightforward, unequivocal identification of mutants with minimal labor (Singer and Yauk, 2010).

The mouse specific-locus test detects recessive mutations that produce easily analyzed, visible phenotypes (coat pigmentation and ear size) conferred by seven genes (Russell and Shelby, 1985; Ehling, 1991; Russell and Russell, 1992; Favor, 1999; Russell, 2004; Singer *et al.*, 2006). Mutants may be classified as having point mutations or chromosomal alterations on the basis of genetic and molecular analysis (Favor, 1999). The assay has been important

in assessing genetic risks of ionizing radiation and has been used to study various chemical mutagens. Although they have been used less extensively, there are other gene mutation assays in mouse germ cells based on dominant mutations that cause skeletal abnormalities (Selby *et al.*, 2004) or cataracts (Ehling, 1991) and recessive mutations that cause electrophoretic changes in proteins (Lewis, 1991).

Mammalian assays permit the measurement of mutagenesis at different germ cell stages (Favor, 1999; Russell, 2004). Late stages of spermatogenesis are often found to be sensitive to mutagenesis, but effects in spermatocytes, spermatids, and spermatozoa are transitory. Mutagenesis in stem-cell spermatogonia and resting oocytes is of special interest in genetic risk assessment because of the persistence of these stages throughout reproductive life. Chemical mutagens show specificity with respect to germ cell stages. For example, ethylnitrosourea and chlorambucil are both potent mutagens in the mouse specific-locus test, but the former induces primarily point mutations in spermatogonia, whereas the latter mostly induces deletions in spermatids (Russell and Russell, 1992). The ratio of deletions to point mutations is not only a function of the nature of the mutagen but depends on germ cell stage, as some mutagens induce higher proportions of gross alterations in late stages of spermatogenesis than in spermatogonia (Lewis, 1991; Favor, 1999; Russell, 2004).

There is currently no unequivocal evidence of induced gene mutations in human germ cells, but studies in mice leave little doubt about the susceptibility of mammalian germ cells to mutagenesis by radiation and chemicals. New molecular methods, particularly those involving the assessment of changes in tandem repeat loci (Yauk, 2004; Dubrova, 2005; Singer *et al.*, 2006; Somers, 2006), hold great promise for the development of systems that will permit the efficient detection of genetic alterations in human germ cells. The development of methods based on expanded simple tandem repeat (ESTR) loci in mice and other species is important, in that it permits *in situ* monitoring for environmental mutagens and the quantification of mutagenesis after controlled exposures of laboratory animals using systems parallel to those being developed for human monitoring (Yauk, 2004; Dubrova, 2005; Wu *et al.*, 2006; Somers, 2006). Basic research on mechanisms underlying ESTR changes is essential, as it is still unclear how ESTR changes relate to the gene mutations that have been long studied by population geneticists and are detected in classical gene-mutation assays.

Chromosomal Alterations Cytogenetic assays in germ cells are not routinely included in mutagenicity testing, but they are an important source of information for assessing risks to future generations posed by the induction of chromosome aberrations. Metaphase analysis of germ cells is feasible in rodent spermatogonia, spermatocytes, or oocytes (Kirkland *et al.*, 1990; Tease, 1992; Russo, 2000; Marchetti *et al.*, 2001). A micronucleus assay has also been developed in which chromosomal damage induced in meiosis is measured by the observation of rodent germ cells, principally spermatids (Russo, 2000; Hayashi *et al.*, 2007).

Aneuploidy originating in mammalian germ cells may be detected cytologically through chromosome counting for hyperploidy (Allen *et al.*, 1986; Adler, 1993; Aardema *et al.*, 1998; Russo, 2000; Marchetti *et al.*, 2001) or genetically in the mouse sex-chromosome loss test (Russell and Shelby, 1985), but these methods are not widely used in toxicological testing. A promising development is the detection of aneuploidy in the sperm of mice or rats by FISH with chromosome-specific probes (Baumgarthner *et al.*, 1999; Russo, 2000; Marchetti *et al.*, 2006, 2008). The presence of two fluorescent spots indicates the presence of an extra copy of the chromosome identified

by the probe; probes for several chromosomes are used simultaneously so that aneuploid sperm are distinguishable from diploid sperm.

Besides cytological observation, indirect evidence for chromosome aberrations is obtained in the mouse heritable translocation assay, which measures reduced fertility in the offspring of treated males (Russell and Shelby, 1985; Singer *et al.*, 2006). This presumptive evidence of chromosomal rearrangements can be confirmed through cytogenetic analysis. Data from the mouse heritable translocation test in postmeiotic male germ cells have been used in an attempt to quantify human germ cell risk for ethylene oxide, a mutagen used as a fumigant, sterilizing agent, and reactant in chemical syntheses (Rhombert *et al.*, 1990; Preston *et al.*, 1995).

Dominant Lethal Mutations The mouse or rat dominant lethal assay (Adler *et al.*, 1994; Singer *et al.*, 2006) offers an extensive database on the induction of genetic damage in mammalian germ cells. In the most commonly used version of the assay, males are treated on an acute or subchronic basis with the chemical of interest and then mated with virgin females at appropriate intervals. The females are killed and necropsied during pregnancy so that embryonic mortality may be characterized and quantified. Most dominant lethal mutations, manifested as intrauterine deaths, are thought to arise from chromosomal anomalies.

Development of Testing Strategies

Concern about adverse effects of mutation on human health, principally carcinogenesis and the induction of transmissible damage in germ cells, has provided the impetus to identify environmental mutagens. Priorities must be set for testing because it is not feasible to conduct multiple tests of all chemicals to which people are exposed. Such factors as production volumes, intended uses, the extent of human exposure, environmental distribution, and effects that may be anticipated on the basis of chemical structure or previous testing must be considered in order to ensure that compounds with the greatest potential for adverse effects receive the most comprehensive study. The most obvious use of genetic toxicology assays is screening chemicals to detect mutagens, but they are also used to obtain information on mutagenic mechanisms and dose–responses that contribute to an evaluation of hazards. Besides testing pure chemicals, environmental samples are tested because many mutagens exist in complex mixtures (DeMarini 1998; Ohe *et al.*, 2003; White, 2004). The analysis of complex mixtures often requires a combination of mutagenicity assays and refined analytical methods (White, 2004; Hewitt and Marvin, 2005). Assessment of a chemical's genotoxicity requires data from well-characterized assays. Assays are said to be validated when they have been shown to perform reproducibly and reliably with many compounds from diverse chemical classes in several laboratories. An evaluation of test performance, however, sometimes extends beyond determining whether the assay effectively detects the specific endpoint that it actually measures to whether it is predictive of other endpoints of interest. For example, there is great interest in the ability of mutagenicity tests, which do not measure carcinogenicity per se, to predict whether chemicals are carcinogens.

Mutagenicity testing, combined with an evaluation of chemical structure, has been found to identify a large proportion of trans-species, multiple-site carcinogens (Tennant and Ashby, 1991; Gold *et al.*, 1993). In contrast, some carcinogens are not detected as mutagens. Putatively nongenotoxic carcinogens often give responses that are more specific with respect to species, sites, and conditions (Ashby and Paton, 1993; Gold *et al.*, 1993). In predicting carcinogenicity, one should consider both the sensitivity and the specificity of an assay. Sensitivity refers to the proportion

of carcinogens that are positive in the assay, whereas specificity is the proportion of noncarcinogens that are negative (Tennant *et al.*, 1987; McGregor *et al.*, 1999). Sensitivity and specificity both contribute to the predictive reliability of an assay. The commonly held view that deficiencies in the sensitivity or specificity of individual assays may be circumvented by using assays in complementary combinations called tiers or batteries has fallen into disfavor because, rather than offsetting each other's strengths and weaknesses, genetic toxicology assays are often consistent with one another (Tennant *et al.*, 1987; Ashby and Tennant, 1991; Kim and Margolin, 1999).

Strategies for testing have evolved over the last few decades, such that data from a few well-chosen assays are now considered sufficient (MacGregor *et al.*, 2000). Rather than trying to assemble extensive batteries of complementary assays, it is prudent to emphasize mechanistic considerations in choosing assays. Such an approach makes a sensitive assay for gene mutations (eg, the Ames assay) and an assay for clastogenic effects in mammals pivotal in the evaluation of genotoxicity, and this is the basis for our highlighting these assays in Table 9-1. The Ames assay has performed reliably with hundreds of compounds in laboratories throughout the world. Other bacterial assays and mammalian cell assays also provide useful information on gene mutations. Beyond gene mutations, one should evaluate damage at the chromosomal level with a mammalian *in vitro* or *in vivo* cytogenetic assay. Cytogenetic assays in rodents are especially useful for this purpose because they combine a well-validated genetic assay with mammalian pharmacodynamics and metabolism. The other assays in Table 9-1 offer an extensive database on chemical mutagenesis (ie, *Drosophila* SLRL), a unique genetic endpoint (ie, aneuploidy; mitotic recombination), applicability to diverse organisms and tissues (ie, DNA damage assays, such as the comet assay), or special importance in the assessment of genetic risk (ie, germ cell assays). The more extensive listing of assays in Table 9-2 provides references that can be helpful in interpreting genetic toxicology data that can be found in the scientific literature.

HUMAN POPULATION MONITORING

For cancer risk assessment considerations, the human data utilized most frequently, in the absence of epidemiologic data, are those collected from genotoxicity/mutagenicity assessments in human populations. For this purpose, the studies conducted most frequently are for chromosome aberrations, micronuclei, mutations (for several loci), and SCEs in peripheral lymphocytes. Cytogenetic alterations have also been assessed in a small number of bone marrow samples. Mutations at the *HPRT* locus have been assessed in peripheral lymphocytes. Glycophorin A variants have been studied in red blood cells.

An important component of any population monitoring study is the selection of the study groups, namely those individuals who are potentially exposed and the matched unexposed controls. The size of each study group should be sufficiently large to avoid any confounder having undue influence. Certain characteristics should be matched among exposed and unexposed groups. These include age, sex, smoking status, and general dietary features. Certain characteristics are exclusionary, namely current or recent medication, radiation exposure, and certain illnesses. It is possible to develop a lengthy list of additional possible confounders of response that would make the selection of suitable study groups very difficult indeed. Study groups of 20 or more individuals can be used as a reasonable substitute for exact matching because confounders will be less influential on chromosome alteration or mutation frequency in

larger groups (discussed in Au *et al.*, 1998; Battershill *et al.*, 2008)). In some instances, it might be informative to compare exposed groups with a historical control, as well as to a concurrent control.

The magnitude of different known confounders varies considerably among studies, based in part on the size of the study populations. Some general indication of the magnitude of the effects of age and smoking status on the frequencies of chromosome aberrations and SCE is presented to illustrate the importance of accounting for confounders in the design of a population monitoring study. The comparisons presented are for large studies only. For chromosome aberrations, the frequency of aberrations has been reported in one large study to be about 50% higher in smokers (1.5 aberrations per 100 cells in smokers vs 1.0 per 100 cells in the nonsmokers) (Galloway *et al.*, 1986) and in another no difference between smokers and nonsmokers (Bender *et al.*, 1988a,b). The complete data set has been reviewed by Au *et al.* (1998). In general, the frequency of SCE is increased by about one SCE per cell in smokers compared with nonsmokers (Bender *et al.*, 1988a,b; Barale *et al.*, 1998). The study by Barale *et al.* (1998) also reported a dose–response association between SCE frequency and smoking level. The differences among these studies might well be accounted for by differences among confounders in the respective groups, but it is virtually impossible to correct for these in this type of study.

The frequency of chromosome aberrations, particularly chromosome-type (reciprocal) exchanges, has been shown to increase with age of subject (Tucker and Moore, 1996). Galloway *et al.* (1986) reported an increase from 0.8 per 100 cells at about 25 years of age to about 1.5 at 60. Bender *et al.* (1988a,b) reported an increase with age only for chromosome-type dicentric aberrations, but the increase over a broad age range was small and just statistically significant. Ramsey *et al.* (1995), using chromosome painting techniques, reported that individuals 50 years and older had frequencies of stable aberrations, dicentrics, and acentric fragments that were 10.6-, 3.3-, and 2.9-fold, respectively, greater than the frequency in cord bloods. Bender *et al.* (1998a,b) did not find an increase in SCE frequency with the increasing age of the subject. The differences among the results from these large control studies emphasize the difficulty of adequately accounting for confounders (age and smoking presented here) when only a small control group is used, as is frequently the case.

Similar sources of variation have been identified for the monitoring of individuals for *HPRT* mutations. The data are reviewed in detail by Albertini and Hayes (1997). There is less information on sources of variation of glycophorin A (GPA) variants, although quite considerable interindividual variation exists (reviewed in Cole and Skopek, 1994; Kyoizumi *et al.*, 2005).

For cytogenetic assays (chromosome aberrations, SCEs, and micronuclei) the alterations are produced as a consequence of errors of DNA replication, as discussed in previous sections. From the nature of the alterations, assessed in traditional cytogenetic assays in which nontransmissible alterations are analyzed, it can be established that these alterations were produced at the first *in vitro* S phase. Irrespective of the duration of exposure, the frequency of cytogenetic alterations will be proportional to that fraction of the DNA damage that remains at the time of *in vitro* DNA replication. All the DNA damage induced by potent clastogens that results in chromosome alterations is repaired within a relatively short time after exposure for G_0 human lymphocytes. Thus, for chronic exposures the lymphocyte cytogenetic assay as typically conducted is insensitive.

It is now possible to analyze reciprocal translocations using FISH methods (reviewed in Tucker *et al.*, 1997; Kleinerman *et al.*, 2006; Beskid *et al.*, 2006), and because this aberration type is

transmissible from cell generation to generation, its frequency can be representative of an accumulation over time of exposure. The importance of this is that stable chromosome aberrations observed in peripheral lymphocytes exposed *in vivo*, but assessed following *in vitro* culture, are produced *in vivo* in hematopoietic stem cells or other precursor cells of the peripheral lymphocyte pool. To date, population cytogenetic monitoring studies involving the analysis of reciprocal translocations in chemically exposed individuals or radiation-exposed individuals have been conducted quite rarely (Lucas *et al.*, 1992; Smith *et al.*, 1998; Kleinerman *et al.*, 2006). The overall sensitivity of the FISH analysis of reciprocal translocations for assessing effects of chronic, low levels of exposure to chemical clastogens has not been established. However, a cautionary note is provided by the study of Director *et al.* (1998), who showed that there was no increase in reciprocal translocations assessed by FISH following exposure to cyclophosphamide (0, 32, 64, or 96 ppm) or urethane (0, 5000, 10,000, or 15,000 ppm) for up to 12 weeks. In contrast, recent data on ethylene oxide (Donner *et al.*, 2010) have shown that exposure of male mice to ethylene oxide at concentrations of 0, 25, 50, 100, 200 ppm for 6, 12, 24, or 48 weeks resulted in a time and concentration-dependent increase in reciprocal translocations assessed by FISH.

Another factor that certainly affects the utility of population monitoring data with reciprocal translocations using FISH is that the frequency of reciprocal translocations increases significantly with increasing age (Ramsey *et al.*, 1995), but to a lesser extent for nontransmissible aberrations (Bender *et al.*, 1988a,b). Ramsey *et al.* (1995) provided data on the influence of other confounders on the frequency of reciprocal translocations in human groups. These confounders include smoking, consumption of diet drinks and/or diet sweeteners, exposure to asbestos or coal products, and having a previous major illness. This reemphasizes the point that the selection of study groups and accounting for confounders is essential for human population cytogenetic monitoring studies to be of utility.

Thus, very few of the published studies of cytogenetic population monitoring for individuals have analyzed the appropriate endpoint for detecting the genetic effects of long-term exposure to chemicals. It is quite surprising that positive responses have been reported for increases in unstable, chromatid aberrations because these are nontransmissible, and as noted above are induced at the first *in vitro* S phase. This anomaly is especially concerning when positive responses at very low levels of exposure are reported (reviewed for ethylene oxide in Preston, 1999b).

The *HPRT* mutation assay can assess the frequency of induced mutations in stem cells or other precursor cells because a proportion of the mutations are induced as nonlethal events. The transmissible proportion will be greater for chemicals that do not induce large deletions; this will include the majority of nonradiomimetic chemicals. Induction of mutations in lymphocyte precursor cells will lead to clonal expansion of mutations in the peripheral pool. However, assessment of the T-cell antigen receptor status of the mutant clones permits a correction for clonal expansion. The population of cells derived from any particular stem cell has a unique antigen receptor status (Albertini and Hayes, 1997). The GPA assay can similarly be used for the assessment of chronic exposures or for estimating exposures at some long time after exposure (Albertini and Hayes, 1997). The predictive value of the assay for adverse health outcome appears to be limited, but it can provide an estimate of exposure.

The potential for cytogenetic endpoints being predictive of relative cancer risk has been addressed in recent reports from the European Study Group on Cytogenetic Biomarkers and Health (Hagmar *et al.*, 1998a,b; Bonassi *et al.*, 2004; Norppa *et al.*, 2006). The groups selected for cytogenetic studies consisted of individuals

with reported occupational exposure and unexposed controls. The association between cancer and the frequency of unstable chromosome aberrations in the study groups was not based on exposure status, but rather on the relative frequency of chromosome aberrations, namely, low (1–33 percentiles), medium (34–66 percentiles), and high (67–100 percentiles). In general, the higher the relative frequency of unstable aberrations, the greater the risk of cancer death for all tumors combined. The authors make it clear that there is insufficient information on exposure for it to be used as a predictor of cancer development. In fact, the data indicate that individuals with higher frequencies of chromosome aberrations for whatever reason (genetic or environmental) are *as a group* at greater risk of dying from cancer. This is very different from concluding that exposures to mutagens that result in a higher frequency of chromosome aberrations in peripheral lymphocytes leads to an increased risk of cancer, especially for specific tumor types. The relevance of exposure to mutagenic chemicals in these studies by Hagmar *et al.* (1998a,b) is uncertain because there was no association between increased SCE frequencies, which may be indicative of higher exposure levels, and increased cancer mortality.

This latter concern was addressed by the same group (Bonassi *et al.*, 2000) in a more recent study. The study again showed that there was a significantly increased risk for subjects with a high level of chromosome aberrations compared to those with a low level in both Nordic and Italian cohorts. Of particular relevance to risk assessment was the observation that the relationships were not affected by the inclusion of occupational exposure level or smoking. The risk for high versus low levels of chromosome aberrations was similar in individuals heavily exposed to carcinogens and in those who had never, to their knowledge, been exposed to any specific environmental carcinogen. These data highlight the need to use caution when considering the relevance of chromosome aberration data from human biomonitoring studies in cancer risk assessment.

NEW APPROACHES FOR GENETIC TOXICOLOGY

In the last 15 or so years, the field of genetic toxicology has moved into the molecular era. The potential for advances in our understanding of basic cellular processes and how they can be perturbed is enormous. The ability to manipulate and characterize DNA, RNA, and proteins has been at the root of this advance in knowledge. However, the development of sophisticated molecular biology does not in itself imply a corresponding advance in the utility of genetic toxicology and its application to risk assessment. Knowing the types of studies to conduct and knowing how to interpret the data remain as fundamental as always. Measuring finer and finer detail can perhaps complicate the utility of the various mutagenicity assays. There is a need for genetic toxicology to avoid the temptation to use more and more sophisticated techniques to address the same questions and in the end make the same mistakes as have been made previously. How successful we are in designing informative studies based on the most recent molecular techniques perhaps cannot be judged at this time. However, the following examples of recent approaches to obtaining data for enhancing our ability to use noncancer (genotoxicity) data in a mechanistically based cancer (and genetic) risk assessment process provide some encouragement. Several recent developments (eg, the refinement of FISH painting, the high-throughput adverse pathway detection approach, and the use of ultrahigh throughput DNA sequencing technologies) have already been described in the appropriate assay sections above because they are currently in general use.

Advances in Cytogenetics

Until quite recently, the analysis of chromosome alterations relied on conventional chromosome staining with DNA stains such as Giemsa or on the process of chromosome banding. Both approaches require considerable expenditure of time and a rather high level of expertise. However, chromosome banding does allow for the assessment of transmissible aberrations such as reciprocal translocations and inversions with a fairly high degree of accuracy. Knowing the induction frequency of such aberrations is very important, given that they are generally not lethal to the cell and constitute by far the major class observed in inherited genetic defects and a significant fraction of the alterations observed in tumors. In addition, because stable aberrations are transmissible from parent to daughter cell, they represent accumulated effects of chronic exposures. The more readily analyzed but cell-lethal, nontransmissible aberrations such as dicentric and deletions reflect only recent exposures and then only when analyzed at the first division after exposure. A more detailed discussion of these factors can be found in Preston (1999b).

The relative ease with which specific chromosomes, specific genes, and chromosome alterations can be detected has been radically enhanced by the development of FISH (Trask *et al.*, 1993; Speicher and Carter, 2005). In principle, the technique relies on amplification of DNA from particular genomic regions such as whole chromosomes or gene regions and the hybridization of these amplified DNAs to metaphase chromosome preparations or interphase nuclei. Regions of hybridization can be determined by the use of fluorescent antibodies that detect modified DNA bases incorporated during amplification or by incorporating fluorescent bases themselves during amplification. The fluorescently labeled, hybridized regions are detected by fluorescence microscopy, and the signal can be increased in strength by computer-enhanced processes. The level of sophistication has increased so much that all 24 different human chromosomes (22 autosomes, X and Y) can be individually detected (Macville *et al.*, 1997), as can all mouse chromosomes (Liyana *et al.*, 1996) (Figs. 9-5 and 9-6). Most recently, M-FISH (multicolor FISH) and M-BAND (multicolor banding) have been developed for defining chromosome abnormalities (Mackinnon and Chudoba, 2011) (Fig. 9-9). Alterations in tumors can also be detected on a whole-genome basis (Coleman *et al.*, 1997; Veldman *et al.*, 1997; Bridge and Cushman-Vokoun, 2011). The following example highlights the ability to construct breakpoint profiles of specific tumor types (Trost *et al.*, 2006). In this example, a detailed analysis by spectral karyotyping of specific breakpoints in a set of primary myelodysplastic syndrome and acute myeloid leukemia samples revealed recurrent involvement of specific chromosome bands that contained oncogenes or tumor-suppressor genes. The aim will be to attempt to reveal the possible prognostic significance of the subgroups linked to these specific markers.

There is an extensive literature on the use of FISH for karyotyping tumors and in gene mapping but less on its utility for genetic toxicology studies, especially the assessment of stable chromosome aberrations at long periods after exposure or after long-term exposures. Three particular studies do, however, serve to exemplify the use of FISH in genetic toxicology.

Lucas *et al.* (1992) demonstrated that stable chromosomal aberrations could be detected in individuals decades after exposure to atomic bombs in Japan. How these frequencies relate to frequencies at the time of exposure is not known with any certainty, given the fact that induced frequencies were not measured because appropriate techniques were not available at that time.

Studies by Tucker *et al.* (1997, 2005) provided some assessment of the utility of FISH for the analysis of radiation-induced,

Figure 9-9. Inversion identified by M-FISH. Region of human chromosomes five stained by M-FISH; the left-hand segment has been inverted as can be seen when compared to the right-hand normal segment. (Reproduced with permission from Hande MP, et al. Past exposure to densely ionizing radiation leaves a unique permanent signature in the genome. *Am J Hum Genet.* 2003; May;72(5):1162–1170.)

stable chromosome alterations at various times after exposure. The frequency of reciprocal translocations induced by γ -rays in rat peripheral lymphocytes decreased with time after exposure, reaching a plateau at four days that was 55% to 65% of the induced frequency and with a dose dependency (Tucker *et al.*, 1997). Similar results were obtained for human samples (Tucker *et al.*, 2005). These results suggest that reciprocal translocations fall into two classes, stable and unstable (cell-lethal). It is quite possible that these “unstable” translocations are lost because of the presence of other cell-lethal damage in the same cell. Additional work is required to clarify this conclusion and to extend the studies to the effects of chemicals. In addition, a recent study by Tucker and Luckinbill (2011) demonstrated how FISH translocation analysis could be used to detect extremely low doses of ionizing radiation—a few centigray per year. Such analysis could be used to estimate responses at very low doses for utility in risk assessments at similarly low doses.

FISH methods have also allowed for an accurate and sensitive assessment of chromosomal alterations present in tumors. The particular advance that makes this assessment feasible is known as comparative genomic hybridization (CGH) (Kallioniemi *et al.*, 1992). CGH results in the ability to identify the role of chromosomal structural and numerical alterations in tumor development. The genomic instability present in all tumor types appears to have a specific genetic basis, as shown elegantly for colon cancer by Vogelstein and colleagues (Cahill *et al.*, 1998). For CGH, tumor and control DNAs are differentially labeled with fluorescence probes and cohybridized to normal metaphase chromosome preparations. The ratio of the fluorescence intensities of hybridized tumor and control DNA indicates regions of normal genomic content as well as those regions that are over- or under-represented in tumors. The CGH method is being adapted for automated screening approaches using biochips (Solinas-Toldo *et al.*, 1997; Hosoya *et al.*, 2006). Assessing genetic alterations such as specific gene deletions in single metastatic tumor cells is

feasible using a slightly different but complementary approach (Pack *et al.*, 1997, 2005).

The types of FISH approaches described here undoubtedly indicate the direction in which cytogenetic analysis will proceed. The types of data collected will affect our understanding of how tumors develop. Data on the dose–response characteristics for a specific chromosomal alteration as a proximate marker of cancer can enhance the cancer risk assessment process by describing effects of low exposures that are below those for which tumor incidence can be reliably assessed. Cytogenetic data of the types described above can also improve extrapolation from data generated with laboratory animals to humans.

Molecular Analysis of Mutations and Gene Expression

With the advent of molecular biology techniques, the exact basis of a mutation at the level of the DNA sequence can be established. In many cases, the genetic basis of human disease can be determined even though human genes have long DNA sequences and a complex genomic arrangement. Molecular biology techniques have also enabled a distinction to be made between background mutations and those induced by specific agents. The latter observations are addressed by analyzing the mutational spectra in target genes in laboratory organisms and in humans (DeMarini, 2000; Hemminki and Thilly, 2004). For reasons of inherent sensitivity of available methods, the genes analyzed for mutations are ones for which mutated forms can be selected. The confounding factor of many normal cells, which far outnumber a few mutant cells in an exposed cellular population, can be removed by mutant selection approaches. Methods to overcome the drawback of only being able to study selectable genes have been developed, and particular ones such as ligation-mediated PCR are close to the required sensitivity level (Albertini and Hayes, 1997; Makrigrigors, 2004; Yeh *et al.*, 2006). For example, COLD-PCR (co-amplification at lower denaturation temperature-PCR) was developed to selectively amplify minority alleles from mixtures of wild-type and mutation-containing sequences (Li and Makrigrigors, 2009).

A giant step forward in the ability to detect and characterize mutations at both the DNA and RNA level has been provided by the development of chip technology (Southern, 1996) and array-based assay systems (Wodicka *et al.*, 1997). With hybridization of test DNAs to oligonucleotide arrays, specific genetic alterations or their cellular consequences can be determined rapidly and automatically (Houlston and Peto, 2004; Vissers *et al.*, 2005). Cost remains a limiting factor, but the potential for assessing specific cellular changes following chemical exposure is enormous. Perhaps of even greater practical importance to the ability to detect mutations is that in the past few years the advent of second- and third-generation ultrahigh throughput DNA sequencing techniques has enormously enhanced the ability to assess mutations quantitatively at the whole genome level in a very short period of time. Such techniques have been used, for example, to characterize the genetic alterations in a number of tumor types (Stratton *et al.*, 2009). Until quite recently, alterations in gene expression following specific exposures or for specific genotypes were analyzed gene by gene. Such an approach makes it difficult to assess changes in gene expression that occur in a concerted fashion. Recent advances using cDNA microarray technologies have allowed the measurement of changes in expression of hundreds or even thousands of genes at one time (Harrington *et al.*, 2000; Elvidge, 2006). The level of expression at the mRNA level is measured by the amount of hybridization of isolated cDNAs to oligonucleotide fragments from known genes or expressed sequence tags (ESTs) on a specifically laid out grid. Although this technique

holds great promise for establishing a cell's response to exposure to chemical or physical agents in the context of normal cellular patterns of gene expression, it remains to be established how to analyze the vast amounts of data that are being obtained and what magnitude of change in gene expression constitutes an adverse effect as far as cellular phenotype is concerned. Extrapolating the responses to organs and whole animals represents a challenge still to be addressed. These microarray-based techniques are now being replaced by massively parallel sequencing or ultrahigh throughput sequencing approaches that can quantitatively assess gene expression changes in response to exposures. Such sequencing-based techniques have the great advantage that they are based on molecule counting approaches rather than on hybridization, thereby making them more quantitative and able to detect very low level transcripts (Blencowe *et al.*, 2009). There are parallel efforts in the area of proteomics and metabolomics whereby changes in a broad range of cellular proteins can be assessed in response to endogenous or exogenous factors, potentially leading to the development of biomarkers of effect (Aebersold *et al.*, 2005; Robertson, 2005; Griffin, 2006; McGregor and Souza, 2006). The biggest hurdle currently is the relative paucity of sequence data available for the world of proteins and their multiple posttranslational modifications. Certainly progress is rapid, and so methodologies akin to gene expression assessment are likely to be close at hand (Xie *et al.*, 2011).

The move in the field of genetic toxicology is away from the "yes/no" approach to hazard identification and much more toward a mechanistic understanding of how a chemical or physical agent can produce adverse cellular and tissue responses. In turn such knowledge can be used for the development of informative bioindicators representing the key events along the pathway from initial interactions with cells to adverse outcome (Jarabek *et al.*, 2009). The move is clearly toward analysis at the whole genome level and away from single gene responses. The challenges are apparent and the solutions are being identified at a rapid pace.

CONCLUSIONS

The field of genetic toxicology has had an overall life of about 70 years and has undergone several rebirths during this period. Genetic toxicology began as a basic research field with demonstrations that ionizing radiations and chemicals could induce mutations and chromosome alterations in plant, insect, and mammalian cells. The development of a broad range of short-term assays for genotoxicity served to identify many mutagens and address the relationship between mutagens and cancer-causing agents, or carcinogens. The inevitable failure of the assays to be completely predictive resulted in the identification of nongenotoxic carcinogens. In the 1980s, genetic toxicology began to move more toward providing insights into a better understanding of the mutagenic mechanisms underlying carcinogenicity and heritable effects. With this improved understanding, genetic toxicology studies began to turn away from hazard identification alone and move toward quantitative risk assessment. Major advances in our knowledge of mechanisms of cancer formation have been fueled by truly amazing progress in molecular biology.

Genetic toxicology has begun to take advantage of the knowledge that cancer is a genetic disease with multiple steps, many of which require a mutation. The identification of chromosome alterations involved in tumor formation has been facilitated greatly by the use of FISH. The ability to distinguish between background and induced mutations, in some cases, can be achieved by mutation analysis at the level of DNA sequence. Second- and third-generation ultrahigh throughput sequencing technologies have allowed such whole genome mutation analysis to be accomplished

in a very short time. Key cellular processes related to mutagenesis have been identified, including multiple pathways of DNA repair, cell cycle controls, and the role of checkpoints in ensuring that the cell cycle does not proceed until the DNA and specific cellular structures are checked for fidelity. These observations have enhanced our knowledge of the importance of genotype in susceptibility to cancer. Recent developments in genetic toxicology have greatly improved our understanding of basic cellular processes and alterations that can affect the integrity of the genetic material and its functions. The ability to detect and analyze mutations in mammalian germ cells continues to improve and can contribute to a better appreciation for the long-term consequences of mutagenesis in human populations. Improvements in the qualitative assessment of mutation in somatic cells and germ cells have been paralleled by advances in the ability to assess genetic alterations quantitatively, especially in ways that enhance the cancer and genetic risk assessment process (Preston, 2005).

ACKNOWLEDGMENTS

The authors thank Drs David DeMarini and Andrew Kligerman for their valuable comments as part of the review of this chapter.

Pathways to the Future

HISTORY

Developmental toxicology encompasses the study of developmental exposures, pharmacokinetics, mechanisms, pathogenesis, and outcomes potentially leading to adverse health effects. Manifestations of developmental toxicity include structural malformations, growth retardation, functional or metabolic impairment, and/or death of the organism. Developmental exposures may also alter the risk of diseases in adulthood. Developmental toxicology defined as such is a relatively new science, but teratology, the study of structural birth defects, as a descriptive science preceded written language. For example, a marble sculpture from southern Turkey dating to 6500 BC depicts conjoined twins (Warkany, 1983), and Egyptian wall paintings of human conditions such as cleft palate and achondroplasia date to as long as 5000 years ago. Conjecture has it that mythological figures such as the Cyclops and sirens took their origin in the birth of malformed infants (Thompson, 1930; Warkany, 1977). Ancient Babylonians, Greeks, and Romans believed that abnormal infants were reflections of celestial events and were considered to be portents of the future. Indeed, the Latin word *monstrum*, from *monstrare* (to show) or *monere* (to warn), connotes an ability to foretell the future. In turn, derivation of the word *teratology* is from the Greek word for monster, *teras*.

Hippocrates and Aristotle thought that abnormal development could originate in physical causes such as uterine trauma or pressure, but Aristotle also held a widespread belief that maternal impressions and emotions could influence the development of the child. He advised pregnant women to gaze at beautiful statuary to increase their child’s beauty. Although this theory sounds fanciful, it is present in diverse cultures throughout recorded history. Indeed, we now know that maternal stress, depression, and anxiety during pregnancy can be deleterious to the developing conceptus and child (Dunkel Schetter and Tanner, 2012).

In 1649, the French surgeon Ambrois Paré expounded upon the theory of Aristotle and Hippocrates by writing that birth defects could result from narrowness of the uterus, faulty posture of the pregnant woman, or physical trauma such as a fall. Fetal limb amputations were thought to result from amniotic bands, adhesions, or twisting of the umbilical cord. This conjecture has proven to be accurate. With the blossoming of biology in the 16th and 17th centuries, scientific theories of causation of birth defects began to emerge. In 1651, William Harvey put forth the theory of developmental arrest, which stated that malformations resulted from incomplete development of an organ or structure. An example given by Harvey was harelip in humans, a congenital malformation that represents a normal developmental stage. Much later, the theory of

developmental arrest was supported by the experiments of Stockard (1921) using eggs of the minnow, *Fundulus heteroclitus*. By manipulating the chemical constituents and temperature of growth media, he produced malformations in the embryos, the nature of which depended on the developmental stage at the time of the insult. He concluded that developmental arrest explained all malformations except those of hereditary origin (Barrow, 1971).

With the advent of the germplasm theory elucidated by Weissmann in the 1880s and the rediscovery of Mendel's laws in 1900, genetics as the basis for some birth defects was accepted. In 1894, Bateson published his treatise on the study of variations in animals as a tool for understanding evolution, inferring that inheritance of such variations could be a basis for speciation (Bateson, 1894). His study contains detailed descriptions and illustrations of such human birth defects as polydactyly and syndactyly, supernumerary cervical and thoracic ribs, duplicated appendages, and horseshoe (fused) kidneys. Bateson coined the term *homeosis* to denote morphological alterations in which one structure takes on the likeness of another. Studies of such alterations in mutants of the fruit fly *Drosophila melanogaster* and, more recently, vertebrates, have served as the basis for much of our present knowledge of the genetic control of development. *Homeobox genes* are found throughout the animal and plant kingdoms and direct embryonic pattern formation (Graham *et al.*, 1989; Deschamps and van Nes, 2005; Mallo *et al.*, 2010). Acceptance of a genetic basis of birth defects was furthered with studies of human inborn errors of metabolism in the first decade of the 20th century.

Modern experimental teratology began in the early 19th century with the work of Etienne Geoffrey Saint-Hilaire. Saint-Hilaire produced malformed chick embryos by subjecting eggs to various environmental conditions including physical trauma (jarring, inversion, pricking) and toxic exposures. In the latter part of the 19th century, Camille Dareste experimented extensively with chick embryos, producing a wide variety of malformations by administering noxious stimuli, physical trauma, or heat shock at various times during development. He found that timing was more important than the nature of the insult in determining the type of malformation produced. Among the malformations described and beautifully illustrated by Dareste (1877, 1891) were the neural tube defects (NTDs) anencephaly and spina bifida, cyclopia, heart defects, situs inversus, and conjoined twins. Many of the great embryologists of the 19th and 20th centuries, including Loeb, Morgan, Driesch, Wilson, Spemann, and Hertwig, performed teratological manipulations employing various physical and chemical probes to deduce principles of normal development.

In the early 20th century, a variety of environmental conditions (temperature, microbial toxins, drugs) were shown to perturb development in avian, reptilian, fish, and amphibian species. In contrast, mammalian embryos were at that time thought to be resistant to induction of malformations, protected from adverse environmental conditions by the maternal system. The first reports to the contrary were published in the 1930s and were the result of experimental maternal nutritional deficiencies. Hale (1935) produced malformations including anophthalmia and cleft palate in offspring of sows fed a diet deficient in vitamin A. Beginning in 1940, Josef Warkany and co-workers began a series of experiments in which they demonstrated that maternal dietary deficiencies and other environmental factors could affect intrauterine development in rats (Warkany and Nelson, 1940; Warkany, 1945; Warkany and Schraffenberger, 1944; Wilson *et al.*, 1953). These experiments were followed by many other studies in which chemical and physical agents, for example, nitrogen mustard, trypan blue, hormones, antimetabolites, alkylating agents, hypoxia, and x-rays, to name a

few, were clearly shown to cause malformations in mammals (see Warkany, 1965).

The first recognized human epidemic of malformations induced by an environmental agent was reported by Gregg (1941), who linked an epidemic of rubella virus infection (German measles) in Australia to an elevation in the incidence of eye, heart, and ear defects, and mental retardation. The triad of deafness, cataracts, and cardiac disease is now recognized as the clinical signature of congenital rubella syndrome. Heart and eye defects predominated with maternal infection in the first or second months of pregnancy, whereas hearing and speech defects and mental retardation were most commonly associated with infection in the third month. Later, the risk of congenital anomalies associated with rubella infection in the first four weeks of pregnancy was estimated to be 61%; in weeks five to eight, 26%; and in weeks nine to 12, 8% (Sever, 1967). It has been estimated that in the United States alone approximately 20,000 children have been impaired as a consequence of prenatal rubella infections (Cooper and Krugman, 1966). Although maternal rubella is now uncommon in developed countries due to vaccination programs, there are still rubella outbreaks in developing countries (De Santis *et al.*, 2006; Chandy *et al.*, 2011), and some cases in developed countries as well (Vauloup-Fellous *et al.*, 2010).

Although embryos of mammals, including humans, were found to be susceptible to common external influences such as nutritional deficiencies and intrauterine infections, the impact of these findings was not fully appreciated at the time (Wilson, 1973). That changed, however, in 1961, when the association between thalidomide ingestion by pregnant women and the birth of severely malformed infants was established (see below).

SCOPE OF PROBLEM: THE HUMAN EXPERIENCE

The overall miscarriage rate in humans is estimated to be 15% to 20% of recognized pregnancies. However, with the development of highly sensitive tests, pregnancies can now be detected shortly after fertilization. When these tests are used early, recognized pregnancy loss increases to about 60% to 70%. Estimates of adverse outcomes include postimplantation pregnancy loss, 31%; major birth defects, 2% to 3% at birth and increasing to 6% to 7% at one year as more manifestations are diagnosed; minor birth defects, 14%; low birth weight, 7%; infant mortality (prior to one year of age), 1.4%; and abnormal neurological function, 16% to 17% (Schardein, 2000). Reasons for these adverse outcomes are largely unknown. Brent and Beckman (1990) attributed 15% to 25% of human birth defects to genetic causes, 4% to maternal conditions, 3% to maternal infections, 1% to 2% to *deformations* (eg, mechanical problems such as umbilical cord limb amputations), <1% to chemicals and other environmental influences, and 65% to unknown etiologies. These estimates are similar to those suggested by Wilson (1977). Regardless of etiology, the sum total represents a significant health burden in light of the over four million births annually in the United States.

It has been estimated that well over 4000 chemicals have been tested in animals for teratogenicity, with approximately 66% shown to be nonteratogenic, 7% teratogenic in more than one species, 18% teratogenic in most species tested, and 9% producing equivocal experimental results (Schardein, 2000). In contrast, only about 35 to 40 chemicals, chemical classes, or conditions (Table 10-1) have been documented to alter prenatal development in humans (Schardein and Keller, 1989; Shepard and Lemire, 2004). A brief review of selected human developmental toxicants provides both a

Table 10-1

Human Developmental Toxicants

Radiation	Drugs and chemicals
Atomic fallout	Aminoglycosides
Radioiodine	Androgenic hormones
Therapeutic	Angiotensin converting enzyme inhibitors: captopril, enalapril
Infections	Angiotensin receptor antagonists: sartans
Cytomegalovirus	Anticonvulsants: Diphenylhydantoin, trimethadione, valproic acid, carbamazepine
Herpes simplex virus I and II	Busulfan
Parvovirus B-19 (erythema infectiosum)	Carbon monoxide
Rubella virus	Chlorambucil
Syphilis	Cocaine
Toxoplasmosis	Coumarins
Varicella virus	Cyclophosphamide
Venezuelan equine encephalitis virus	Cytarabine
Maternal trauma and metabolic imbalances	Diethylstilbestrol
Alcoholism	Danazol
Amniocentesis, early	Ergotamine
Chorionic villus sampling (before day 60)	Ethanol
Cretinism	Ethylene oxide
Diabetes	Fluconazole
Folic acid deficiency	Folate antagonists: aminopterin, methotrexate
Hyperthermia	Iodides
Phenylketonuria	Lead
Rheumatic disease and congenital heart block	Lithium
Sjogren syndrome	Mercury, organic
Virilizing tumors	Methimazole
	Methylene blue
	Misoprostal
	Penicillamine
	Polychlorobiphenyls
	Quinine (high dose)
	Retinoids: Accutane, isotretinoin, tretinate, acitretin
	Tetracyclines
	Thalidomide
	Tobacco smoke
	Toluene
	Vitamin A (high dose)

SOURCES: Data from Shepard (2004) and Schardein and Macina (2007).

historical view of developmental toxicology and an illustration of some of the key principles of the science.

Thalidomide

In 1960, a striking increase in newborns with rare limb malformations was recorded in West Germany. The affected individuals had amelia (absence of the limbs) or various degrees of phocomelia (reduction of the long bones of the limbs), usually affecting the arms more than the legs and usually involving both left and right sides, although to differing degrees. Congenital cardiac, ocular, otic, intestinal, and renal anomalies were also involved. However, the limb defects were pathognomonic, as limb reduction anomalies of this nature are exceedingly rare. At the university clinic

in Hamburg, for example, no cases of phocomelia were reported between 1940 and 1959. In 1959 there was a single case; in 1960, there were 30 cases; and in 1961, a total of 154 cases (Taussig, 1962). The unusual nature of the malformations was a key factor in unraveling the epidemic. In 1961, Lenz and McBride, working independently in Germany and Australia, respectively, identified the sedative thalidomide as the causative agent (McBride, 1961; Lenz, 1961, 1963). Thalidomide had been introduced in 1956 by Chemie Grunenthal as a sedative/hypnotic and was used throughout much of the world as a sleep aid and to treat nausea and vomiting in pregnancy. The drug was widely prescribed at an oral dose of 50 to 200 mg/day. There were a few reports of peripheral neuritis attributed to thalidomide, but only in patients with long-term use for up to 18 months (Fullerton and Kermer, 1961). Following the association with birth defects, thalidomide was withdrawn from the market by Grunenthal in November 1961, and case reports ended in mid-1962 as exposed pregnancies were completed. Estimates of the number of infants malformed by thalidomide worldwide during this period range from 5840 (Lenz, 1988) to over 10,000 in 46 countries (Bartlett *et al.*, 2004). Quantitative estimates of malformation risks from exposure have been difficult to compile but are believed to be in the range of one in two to one in 10 (Newman, 1985). Due to concerns regarding the severity of the peripheral neuritis and subsequent questions with regard to safety in pregnancy, thalidomide did not receive marketing approval by the US Food and Drug Administration (FDA) prior to its removal from the world market following the epidemic. Much credit is due to Dr Frances Kelsey, who was a new FDA staff member at the time. She later received the highest honor that can be bestowed upon a US civilian, the medal for Distinguished Federal Civilian Service, from President John F. Kennedy, for her diligence in protecting the country.

As a result of the thalidomide catastrophe, regulatory agencies in many countries began developing animal testing requirements for evaluating the effects of drugs during pregnancy (Stirling *et al.*, 1997). In the United States, the discussions ultimately led to the development of the Segment I, II, and III testing protocols of the FDA (Kelsey, 1988). Current regulatory testing guidelines for developmental toxicity are discussed later in this chapter.

It is both ironic and telling that the chemical largely responsible for the advent of modern regulation of potential developmental toxicants presents a complex pattern of effects in different animal species. It has been tested for prenatal toxicity in at least 19 laboratory species. Malformations and increased embryonic loss have been observed in some studies in rats, whereas generally no effects were reported in studies with hamsters or most mouse strains. Effects more or less similar to those observed in humans have been reported for several rabbit strains and in eight of nine primate species. The teratogenic potency of thalidomide ranges from approximately 1 to 100 mg/kg among sensitive species. In this ranking the human sensitivity was estimated to be 1 mg/kg (Schardein, 1993).

Studies of the relationship between timing of drug use and type of malformation revealed that thalidomide was teratogenic between 20 and 36 days after fertilization (Lenz and Knapp, 1962). Because of its short half-life, teratogenic potency, and good records/recall of prescribed drug use, fairly concise timetables of susceptibility have been constructed (Lenz and Knapp, 1962; Nowack, 1965; Neubert and Neubert, 1997; Miller and Stromland, 1999). During the susceptible period of 20 to 36 days postfertilization, anotia (missing ear) was the defect induced earliest, followed by thumb, upper extremity, lower extremity, and triphalangeal thumb (Miller and Stromland, 1999). Despite extensive effort, research to understand the species and strain differences in response to thalidomide has met with limited success until recently. Extensive structure–activity

studies involving analogs of thalidomide found strict structural requirements (eg, an intact phthalimide or phthalimidine group) but shed little light on potential mechanisms (Jonsson, 1972; Schumacher, 1975; Helm *et al.*, 1981). Stephens (1988) reviewed 24 proposed mechanisms, including biochemical alterations involving vitamin B, glutamic acid, acylation, nucleic acids, and oxidative phosphorylation; cellular mechanisms including cell death and cell–cell interactions; and tissue level mechanisms including inhibition of nerve and blood vessel outgrowth. None was considered sufficient by that reviewer. More recent hypotheses concerning the mechanism of thalidomide teratogenesis include effects on angiogenesis (D'Amato *et al.*, 1994; Joussem *et al.*, 1999; Sauer *et al.*, 2000; Stephens *et al.*, 2000; Therapontos *et al.*, 2009), integrin regulation (Neubert *et al.*, 1996), oxidative DNA damage (Parman *et al.*, 1999), TNF- α inhibition (Argiles *et al.*, 1998), growth factor antagonism (Stephens *et al.*, 1998; Stephens and Fillmore, 2000), effects on glutathione and redox status (Hansen *et al.*, 1999), and inhibition of ubiquitin-mediated protein degradation (Ito *et al.*, 2011; Ito and Handa, 2012).

The idea that thalidomide exerts its teratogenicity in sensitive species by altering cellular redox status has been explored by Wells and colleagues (Parman *et al.*, 1999), who compared the effects of thalidomide in the pregnant mouse (an insensitive species) and the pregnant rabbit (a sensitive species). First, they demonstrated a 380% increase in DNA oxidation in rabbit embryos. Pretreatment of pregnant rabbits with the spin-trapping (free-radical scavenging) agent α -phenyl-*N*-*t*-butylnitron (PBN) reduced thalidomide-induced embryonal DNA oxidation by 73%. Thalidomide was teratogenic and embryotoxic in the rabbit, inducing characteristic limb defects as well as other malformations, embryo/fetal mortality, and reduced fetal weight. Almost all of these effects on the rabbit embryos were abolished by maternal pretreatment with PBN. These results indicate that, in the rabbit, thalidomide is activated to a free-radical intermediate that initiates the formation of reactive oxygen species that appear to be a key element of the mechanism of teratogenicity because both oxidation and teratogenicity are largely reduced by PBN. This group has recently demonstrated limb bud embryopathies in rabbit embryos cultured in medium containing thalidomide or two of its hydrolysis products, with concomitant DNA oxidation (Lee *et al.*, 2011). Although oxidation of DNA may be part of the teratogenic mechanism of thalidomide, Hansen and Harris (2004) have provided strong evidence to support their hypothesis that the limb defects induced by thalidomide are due to misregulation of the expression of genes critical for the outgrowth of the limb. They too have shown that thalidomide causes oxidative stress in sensitive (rabbit) but not in resistant (rat) pregnant animals and their embryos, by comparing glutathione depletion following administration of thalidomide (Hansen *et al.*, 2002). They further demonstrated that this shift in redox potential reduces binding of a key transcription factor, NF- κ B, to its binding sites on DNA. Binding of NF- κ B is required to turn on the expression of the genes *twist* and *FGF-10* in the mesenchyme of the developing limb. Lack of expression of these two genes resulted in loss of *FGF-8* expression in the apical ectodermal ridge of the developing limb bud. Given our understanding of the importance of these genes for normal limb development, ablation of their expression by thalidomide could be predicted to cause the limb defects seen in sensitive species. That these genes are under the control of the redox-sensitive NF- κ B may be the basis for the differences in teratogenicity of thalidomide in the sensitive rabbit (and presumably human) and the resistant mouse and rat.

Research on alterations in immune function and angiogenesis has opened the possibility of expanded use of thalidomide

in diseases including dermatological disorders, arthritis, multiple myeloma, diabetic retinopathy, and macular degeneration (Adler, 1994; Calabrese and Fleischer, 2000; Schwab and Jagannath, 2006; Chen *et al.*, 2010). Thalidomide has been approved by the FDA for erythema nodosum leprosum, an inflammatory complication of Hansen disease (leprosy) and multiple myeloma. In addition, it is used off-label for a number of disorders. An unprecedented level of safeguards, embodied in the STEPS program (System of Thalidomide Education and Prescribing Safety: http://www.thalomid.com/steps_program.aspx), surrounds thalidomide use to prevent accidental exposure during pregnancy, including required registration of all prescribers, pharmacies, and patients, required use of contraception, and periodic pregnancy testing for patients of childbearing ability (Lary *et al.*, 1999).

Diethylstilbestrol

Diethylstilbestrol (DES), a synthetic nonsteroidal estrogen, was widely used from the 1940s to the 1970s in the United States to prevent miscarriage by stimulating synthesis of estrogen and progesterone in the placenta. Between 1966 and 1969, seven young women between the ages of 15 and 22 were seen at Massachusetts General Hospital with clear cell adenocarcinoma of the vagina. This tumor had not previously been seen in patients younger than 30. An epidemiological case–control study subsequently found an association with first trimester DES exposure (reviewed in Poskanzer and Herbst, 1977). The Registry of Clear Cell Adenocarcinoma of the Genital Tract of Young Females was established in 1971 to track affected offspring. Maternal use of DES prior to the 18th week of gestation appeared to be necessary for induction of the genital tract anomalies in offspring. The incidence of genital tract tumors peaked at age 19 and declined through age 22, with absolute risk of clear cell adenocarcinoma of the vagina and cervix estimated to be 0.14 to 1.4 per 1000 exposed pregnancies (Herbst *et al.*, 1977). However, the overall incidence of noncancerous alterations in the vagina, cervix, and uterus was estimated to be as high as 75% (Poskanzer and Herbst, 1977). Effects of developmental exposure on the female reproductive tract may be due to alterations in genetic pathways governing uterine differentiation (Huang *et al.*, 2005). In male offspring of exposed pregnancies, epididymal cysts, hypotrophic testes, and capsular induration along with low ejaculated semen volume and poor semen quality have been observed (Bibbo *et al.*, 1977). The realization of the latent and devastating manifestations of prenatal DES exposure has broadened our concept of the magnitude and scope of potential adverse outcomes of intrauterine exposures. Yet, recent studies suggest even broader developmental targets; a study in mice by Newbold *et al.* (2006) showed that the increased susceptibility to tumors and reproductive tract abnormalities conferred by DES exposure may be passed on to future generations (both males and females) of exposed mothers. Developmental exposure to DES has also been shown to cause obesity in mice (Newbold *et al.*, 2009).

Ethanol

The developmental toxicity of ethanol has been a recurrent concern throughout history and can be traced to biblical times (eg, Judges 13: 3–4). Yet, only since the description of the Fetal Alcohol Syndrome (FAS) by Jones and Smith in the early 1970s (Jones and Smith, 1973; Jones *et al.*, 1973) has there been a clear recognition and acceptance of alcohol's developmental toxicity. Since that time, there have been hundreds of clinical, epidemiological, and experimental studies of the effects of ethanol exposure during

gestation, revealing an ever-widening array of effects of alcohol on development (for review, see Jones, 2011).

The FAS comprises craniofacial dysmorphism, intrauterine and postnatal growth retardation, retarded psychomotor and intellectual development, and other nonspecific major and minor abnormalities (Abel, 1982, 2006; Jones, 2011). The average IQ of FAS children has been reported to be 68 (Streissguth *et al.*, 1991a) and changes little over time (Streissguth *et al.*, 1991b). The craniofacial malformations as well as other morphological and anatomical effects of prenatal ethanol exposure may be due, at least in part, to interference with retinol metabolism in the early embryo, at a time when the anterior part of the embryo, including the brain, is just beginning to form (Yelin *et al.*, 2005). Oxidation of retinol to the signaling molecule, retinoic acid, is crucial for normal development of the embryo. However, the molecular mechanisms underlying FAS are still poorly understood, and the possible molecular and cellular targets are many (eg, Sulik, 2005; Smith, 2010; Zeisel, 2011).

Full-blown FAS has been observed primarily in children born to alcoholic mothers, and among alcoholics the incidence of FAS has been estimated at 25 per 1000 (Abel, 1984). Numerous methodological difficulties are involved in attempting to estimate the level of maternal ethanol consumption associated with FAS, but estimates of a minimum of 3 to 4 oz of alcohol per day have been made (Clarren *et al.*, 1987; Ernhart *et al.*, 1987).

Decades of research has demonstrated that FAS represents an extreme of the range of effects of developmental alcohol exposure, now termed fetal alcohol spectrum disorders (FASDs) (Koren *et al.*, 2003; Sokol *et al.*, 2003; Manning and Hoyme, 2007; Hellemans *et al.*, 2010). In utero exposure to lower levels of ethanol has been associated with a wide range of effects, including isolated components of FAS and effects on the developing brain leading to cognitive and behavioral deficits. Little (1977) studied 800 women prospectively to evaluate the effects of drinking on birth weight. After adjusting for smoking, gestational age, maternal height, age, parity, and sex of the child, it was found that for each ounce of absolute ethanol consumed per day during late pregnancy there was a 160-g decrease in birth weight. Effects of maternal alcohol consumption during pregnancy on attention, short-term memory, and performance on standardized tests have been noted in a longitudinal prospective study of 462 children (Streissguth *et al.*, 1994a,b). Alcohol intake was related to decrements in these measures, the number of drinks per drinking occasion being the strongest predictor. Streissguth and co-workers (Baer *et al.*, 2003) have also reported that prenatal alcohol exposure was significantly associated with alcohol drinking problems at age 21, independent of family history or other environmental factors. Later life vulnerability to stress, depression, and anxiety disorders after in utero exposure to alcohol are reviewed by Hellemans *et al.* (2010). For reviews of the neurotoxic effects of developmental ethanol exposure, see the special issue of *Neuropsychology Review* (June 2011;21(2)) on this topic.

One animal model of FAS in which pathogenesis of the craniofacial effects has been extensively studied involves intraperitoneal injection of ethanol to pregnant C57Bl/6J mice in early pregnancy when embryos are undergoing *gastrulation* (Sulik *et al.*, 1981; Sulik and Johnston, 1983). Following such exposures, term fetuses exhibit many of the features of FAS, including microcephaly, microphthalmia, short palpebral fissures, deficiencies of the philtral region, and a long upper lip. The specific set of craniofacial malformations produced in offspring depends on the time of exposure. Excess cell death in sensitive cell populations is a common finding (Kotch and Sulik, 1992; Sulik, 2005; Smith, 2010).

Figure 10-1. Effects of maternal smoking on pregnancy and offspring. These are effects for which dose–response relationships with maternal smoking have been established, but do not represent all of the effects of maternal smoking during pregnancy (see Rogers, 2008). (Plotted data are from: Preterm birth (spontaneous delivery at 33–36 weeks gestation), Kyrklund-Blomberg and Cnattingius (1998); small-for-gestational age (SGA, <10th percentile for gestational week) from Windham *et al.* (2000); stillbirth from Wisborg *et al.* (2001); ectopic pregnancy from Handler *et al.* (1989); sudden infant death syndrome (SIDS) from Fleming and Blair (2007); offspring type 2 diabetes from Montgomery and Ekblom (2002), offspring obesity (BMI > 97 percentile), Von Kries *et al.* (2002)).

Tobacco Smoke

Prenatal and early postnatal exposure to tobacco smoke or its constituents may well represent the leading cause of environmentally induced developmental disease and morbidity today (Rogers, 2008) (Fig. 10-1). Approximately 25% of women in the United States continue to smoke during pregnancy, despite public health programs aimed at curbing this behavior. Because of the high number of pregnant smokers and the relative accuracy of assessing smoking during pregnancy, results of epidemiological studies provide a well-characterized picture of the consequences of developmental tobacco smoke exposure. These include spontaneous abortions, perinatal deaths, sudden infant death syndrome (SIDS), learning, behavioral, and attention disorders, and lower birth weight (Slotkin, 1998; Fried *et al.*, 1998; Tuthill *et al.*, 1999; Haug *et al.*, 2000; Markussen Linnet *et al.*, 2006; Rogers, 2008). In a review of smoking and SIDS (Mitchell and Milerad, 2006), the relative risk associated with maternal smoking was 2.86 (95% confidence interval 2.77–2.95) before prone sleep-position intervention (putting infants on their backs for sleep reduces the overall risk of SIDS) and 3.93 (3.78–4.08) after intervention programs were started. The authors of the review estimated that about one-third of SIDS deaths might have been prevented if no fetuses had been exposed in utero to maternal smoking. Recent studies have found that offspring of smoking mothers have a higher risk of obesity, hypertension, and type 2 diabetes than offspring of nonsmokers (Oken *et al.*, 2008; Suzuki *et al.*, 2009; Bakker and Jaddoe, 2011; Cupul-Uicab *et al.*, 2012).

Maternal smoking has not been associated with a high risk of structural malformations. However, Hackshaw *et al.* (2011) performed a systematic review and meta-analysis of observational studies reporting odds ratios for having a nonchromosomal birth defect for women who smoked versus nonsmokers. There were 172 published articles comprising 173,687 malformed cases and 11.7 million controls considered in the review. Significant positive associations with maternal smoking were found for these defects

[odds ratios]: cardiovascular [1.09], musculoskeletal [1.16], limb reduction [1.26], missing/extra digits [1.18], clubfoot [1.28], craniosynostosis [1.33], facial [1.19], eye [1.25], orofacial clefts [1.28], gastrointestinal [1.27], gastroschisis [1.5], anal atresia [1.20], hernia [1.40], and undescended testes [1.13]. Lammer and co-workers (Lammer *et al.*, 2005) found that maternal smoking was a risk factor for orofacial clefts, and increased risk is associated with particular genotypes indicating lack of enzymes involved in detoxification of smoking-derived chemicals. Gene–environment interactions may also be the basis for increased risk of other birth defects with maternal smoking (Shi *et al.*, 2008). Perinatal exposure to tobacco smoke can also affect branching morphogenesis and maturation of the lung, leading to altered physiological function (Pinkerton and Joad, 2000; Gilliland *et al.*, 2000; Maritz and Harding, 2011). In a genome-wide association study, two genes, *TBK1* on chromosome 12 and *ZNF236* on chromosome 18, showed multiple single nucleotide polymorphisms associated with higher risk of nonsyndromic cleft palate in the presence of maternal smoking (Beaty *et al.*, 2011). One component of tobacco smoke, nicotine, is a known neuroteratogen in experimental animals and can by itself produce many of the adverse developmental outcomes associated with tobacco smoke, including impaired fertility, neurobehavioral effects, respiratory dysfunction, obesity, hypertension, and type 2 diabetes (Slotkin, 1998; Bruin *et al.*, 2010).

It is important to state unequivocally that exposure to environmental (secondhand) tobacco smoke also represents a significant risk to the pregnant nonsmoker and her baby, and exposure to secondhand smoke has been associated with many of the effects caused by active maternal smoking (eg, Windham *et al.*, 2000; George *et al.*, 2006; Mitchell and Milerad, 2006). In a literature review with meta-analysis, Leonardi-Bee and co-workers (2008) found that exposure of nonsmoking pregnant women to secondhand smoke was associated with reduction of birth weight by 33 g or more, as well as a 22% increased risk of being of low birth weight (<2500 g). In a subsequent review and meta-analysis (Leonardi-Bee *et al.*, 2011), they found that nonsmoking pregnant women exposed to secondhand tobacco smoke were 23% more likely to experience stillbirth and 13% more likely to have a child with a congenital malformation.

Cocaine

Cocaine, a plant alkaloid derived from coca, is a local anesthetic with vasoconstrictor properties. Effects on the fetus are complicated and controversial and demonstrate the difficulty of monitoring the human population for adverse reproductive outcomes (reviewed in Scanlon, 1991; Volfe, 1992; Addis *et al.*, 2001; Ackerman *et al.*, 2010). Accurate exposure ascertainment is difficult, as many confounding factors, including socioeconomic status and concurrent use of cigarettes, alcohol, and other drugs of abuse, may be involved. In addition, reported effects on the fetus and infant (neurological and behavioral changes) are difficult to identify and quantify. Cocaine exposure during pregnancy in humans appears to be associated with abruptio placentae (Addis *et al.*, 2001), and preterm birth, low birth weight, and small-for-gestational age (SGA) infants (Gouin *et al.*, 2011). Congenital malformations of the genitourinary tract have also been reported (Lutiger *et al.*, 1991), and kidney and bladder function is diminished in fetuses of pregnant women using cocaine (Mitra, 1999). Moreover, fetal cocaine exposure has been associated with impaired neonatal auditory processing (Potter *et al.*, 2000). Fetal cocaine exposure can be estimated by chemical analysis of fetal meconium, which can provide a measure of developmental exposure to xenobiotic agents

ranging from food additives to over-the-counter medications to drugs of abuse (Ostrea *et al.*, 1998).

Retinoids

The ability of excess vitamin A (retinol) to induce malformations has been known for at least 50 years (Cohlan, 1954). Effects on the developing embryo include malformations of the face, limbs, heart, central nervous system, and skeleton. Similar malformations were later shown to be induced by retinoic acid (RA) administration in the mouse (Kochhar, 1967) and hamster (Shenefelt, 1972). Since those observations, knowledge relating to the effects of retinol, RA, and structurally related chemicals that bind to and activate specific nuclear receptors has expanded rapidly (Chambon, 1994; Lohnes *et al.*, 1994; Mendelsohn *et al.*, 1994; Collins and Mao, 1999; Arafa *et al.*, 2000). The RXR- α receptor appears to play an important role in cleft palate induced by RA (Nugent *et al.*, 1999). The teratogenic effects of vitamin A and retinoids have been reviewed (Nau *et al.*, 1994; Collins and Mao, 1999).

Beginning in 1982, one retinoid, 13-*cis*-RA (isotretinoin or Accutane), was marketed as an effective treatment of cystic acne. Despite clear warnings against use in pregnancy on the label of this prescription drug (FDA pregnancy category X: proven fetal risks clearly outweigh any benefit), an extensive physician and patient education program, and restrictive requirements for prescription to women of childbearing potential, infants with pathognomonic malformations involving the ears, heart, brain, and thymus were reported as early as 1983 (Rosa, 1983; Lammer *et al.*, 1985). Among 115 exposed pregnancies not electively terminated, 18% ended in spontaneous abortion and 28% of live-born infants had at least one major malformation (Dai *et al.*, 1992). In another prospective study, there was nearly a doubling of the risk for premature delivery after first trimester exposure, and about 50% of the exposed children had full-scale IQ scores below 85 at age five (Lammer, 1992). Robertson *et al.* (2005) reported that almost 25% of women with an isotretinoin-exposed pregnancy did not recall having contraception counseling before starting their medication. Rates of recommended birth control and monthly pregnancy testing were low. Thus, voluntary pregnancy prevention programs for women receiving prescriptions for isotretinoin were not highly effective, resulting in fetal exposures to isotretinoin. Adams (2010) has reviewed the neurobehavioral teratology of retinoids over the last 50 years.

Antiepileptic Drugs

Clinical management of women of childbearing age who have epilepsy is difficult. Although control of seizures during pregnancy is crucial, most current antiepileptic drugs (AEDs) have been shown to carry risk of developmental toxicity including birth defects, cognitive impairment, and fetal death. As a class, including phenytoin, carbamazepine and valproic acid, AEDs are considered human teratogens. These drugs can be used as monotherapy or in combination. In general, the incidence of birth defects increases with the number of drugs used in combination. Newer AEDs such as gabapentin, lamotrigine, oxcarbazone, topiramate, and zonisamide have now been used for over a decade, and studies to date suggest that these alternatives may be safer than the older AEDs. The interested reader is directed to several recent reviews (Tatum, 2006; Tomson and Battino, 2005; Ornoy, 2006; Hansen, 2010).

Phenytoin (diphenylhydantoin) has been used as an AED for over 70 years and its antiepileptic effect occurs through inhibition of voltage-gated sodium channels. It is metabolized by the cytochrome P450 system to a reactive intermediate and then to an active

metabolite that is excreted in the urine. The fetal hydantoin syndrome, described by Hanson and Smith (1975), includes craniofacial abnormalities, limb defects, growth deficiency, and mild-to-moderate mental retardation. This syndrome has been reported to occur in 5% to 10% of exposed offspring (Schardein, 2000). Proposed mechanisms involved in the teratogenicity of phenytoin include folic acid deficiency and the formation of reactive intermediates that damage tissue macromolecules (for review see Hansen, 2010).

Carbamazepine has been reported to be teratogenic in rats and mice (Schardein, 2000), and a report from the FDA (Rosa, 1991) linked the drug to NTDs in humans. A meta-analysis of 16 studies reported a 2.89-fold increased risk of a major birth defect in offspring of pregnant women treated with carbamazepine (Matalon *et al.*, 2002). An epoxide metabolite of carbamazepine was found to be teratogenic in mice *in vivo* (Bennett *et al.*, 1996) but not in mice or rats *in vitro* (Hansen *et al.*, 1996). The teratogenicity observed in mice may have been related to maternal toxicity or to a different metabolite.

Valproic acid, or 2-propylpentanoic acid, was first marketed in Europe in 1967 and in the United States in 1978. In 1982, Elizabeth Robert reported that, of 146 cases of spina bifida aperta recorded in Lyon, France, nine of the mothers had taken valproic acid during the first trimester of pregnancy. The odds ratio in a case-control study was 20.6, and the estimated risk of a valproate-exposed woman having a child with spina bifida was 1.2%, a risk similar to that for women with a previous child with an NTD (Centers for Disease Control and Prevention [CDC], 1982). The report was quickly confirmed in other areas of the world through the efforts of the International Clearinghouse of Birth Defect Registries (CDC, 1983). It was fortunate that several events came together to allow the determination of valproate as a human teratogen. These included the active birth defects registry, an interest by Robert in the genetics of spina bifida, a question on epilepsy and anticonvulsant use in a Robert survey, and the prevalence of valproate monotherapy for epilepsy in that region (Lammer *et al.*, 1987). These findings spurred a great deal of research on the effects of valproate in multiple species, including the effects of enantiomers of valproate analogs. Yet, the mechanism of action, as for most developmental toxicants, remains elusive (Nau *et al.*, 1991; Ehlers *et al.*, 1992a,b; Hauck and Nau, 1992). Use of inbred mouse strains differing in their sensitivity to valproate-induced teratogenesis has revealed several candidate genes conferring sensitivity (Finnell *et al.*, 1997, 2000; Craig *et al.*, 2000; Bennett *et al.*, 2000). Similar to phenytoin, some studies have indicated a possible role of interference with folate metabolism (Hansen, 2010). Valproic acid is also a histone deacetylase inhibitor, and this may play a role in its teratogenicity (Menegola *et al.*, 2006; Eikel *et al.*, 2006).

Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Antagonists

The renin-angiotensin system is a key controller of blood pressure. The active signaling messenger of this system is angiotensin II, which binds to angiotensin II (AT1) receptors to cause vasoconstriction and fluid retention, resulting in elevation of blood pressure. Antihypertensive agents acting on this system include the angiotensin-converting enzyme (ACE) inhibitors and the AT1 receptor blockers (collectively known as “sartans”). ACE inhibitors are widely prescribed and, when used in the second half of pregnancy, are known to cause oligohydramnios (low amniotic fluid volume), fetal growth retardation, pulmonary hypoplasia, joint contractures, hypocalvaria, neonatal renal failure, hypotension, and death. Angiotensin II receptor antagonists taken during the same

period (second or third trimester) in pregnancy cause a similar spectrum of developmental toxicity (Friedman, 2006; Quan, 2006). These findings in the fetus can be related to the reduced amniotic fluid volume, a consequence of impaired fetal renal function (Tabacova, 2005). The developmental toxicity of first trimester use of ACE inhibitors and AT1 receptor antagonists has been somewhat controversial (Schaefer, 2003), although a recent study found an increased risk of major congenital malformations following first trimester exposure to ACE inhibitors (Cooper *et al.*, 2006). These authors studied a cohort of 29,507 infants born between 1985 and 2000. Of these, 209 infants had exposure to ACE inhibitors in the first trimester alone. These infants had an increased risk of major congenital malformations (relative risk = 2.71, 95% confidence interval 1.72–4.27). The risk ratio for malformations of the cardiovascular system and the central nervous system were 3.72 and 4.39, respectively. These authors concluded that exposure to ACE inhibitors during the first trimester should be avoided. However, a recent literature review and meta-analysis of studies of first trimester exposures to ACE inhibitors and AT1 blockers found that while there was a significant increase in risk of major malformations compared to healthy controls, the risk was similar to that of patients on other antihypertensives (Walfisch *et al.*, 2011). These results suggest that a first trimester exposure to antihypertensives in general may be teratogenic.

PRINCIPLES OF DEVELOPMENTAL TOXICOLOGY

Principles of teratology were put forth by James Wilson in 1959 and in his watershed monograph *Environment and Birth Defects* (Wilson, 1973) (Table 10-2). Much progress has been made in the ensuing decades, yet these principles have withstood the test of time and remain basic to developmental toxicology.

Critical Periods of Susceptibility and Endpoints of Toxicity

Familiarity with principles of normal development is a prerequisite to understanding abnormal development. Development is characterized by change: change in size, changes in biochemistry and physiology, and changes in form and functionality. These changes

Table 10-2

Wilson General Principles of Teratology

- I. Susceptibility to teratogenesis depends on the genotype of the conceptus and the manner in which this interacts with adverse environmental factors.
- II. Susceptibility to teratogenesis varies with the developmental stage at the time of exposure to an adverse influence.
- III. Teratogenic agents act in specific ways (mechanisms) on developing cells and tissues to initiate sequences of abnormal developmental events (pathogenesis).
- IV. The access of adverse influences to developing tissues depends on the nature of the influence (agent).
- V. The four manifestations of deviant development are death, malformation, growth retardation, and functional deficit.
- VI. Manifestations of deviant development increase in frequency and degree as dosage increases, from the no effect to the totally lethal level.

are orchestrated by a cascade of factors regulating gene expression, the first of which are maternally inherited and present in the egg prior to fertilization. In turn, these maternal factors activate regulatory genes in the embryonic genome, and sequential gene activation continues throughout development. Intercellular and intracellular signaling pathways essential for normal development have been elucidated and rely on transcriptional, translational, and posttranslational controls.

Because of the rapid changes occurring during development, the nature of the embryo/fetus as a target for toxicity is also changing. Although the basic tenets of toxicology discussed elsewhere in this text also apply during development, the principle of critical periods of sensitivity based on developmental stage of the conceptus at the time of insult is a primary and somewhat unique consideration. In this section, normal developmental stages are discussed in the context of their known and potential susceptibility to toxicants. It should be emphasized, however, that development is a continuum; these stages are used for descriptive purposes and do not necessarily represent discrete developmental events. Timing of some key developmental events in humans and experimental animal species is presented in Table 10-3.

As a logical starting point, *gametogenesis* is the process of forming the haploid germ cells or gametes, the egg and sperm. These gametes fuse in the process of fertilization to form the diploid *zygote*, or one-celled embryo. Gametogenesis and fertilization are vulnerable to toxicants, but this is the topic of another chapter in this text. It is now known that the maternal and paternal genomes are not equivalent in their contributions to the zygotic genome. The process of *imprinting* occurs during gametogenesis, conferring to certain allelic genes a differential expressivity depending

on whether they are of maternal or paternal origin (Latham, 1999; Li and Sasaki, 2011). Because imprinting involves cytosine methylation and changes in chromatin conformation, this process may be susceptible to toxicants that affect these targets (Murphy and Jirtle, 2000). Jirtle and colleagues have demonstrated that both early nutrition (Waterland and Jirtle, 2003, 2004) and the estrogenic compound genistein (Dolinoy *et al.*, 2006) can modify the methylation patterns of specific genes and cause altered phenotypes in mice. Anway *et al.* (2006) demonstrated a transgenerational effect of the fungicide vinclozolin in rats, in which male offspring (F1) of treated F0 females had reduced spermatogenic capacity, which was transmitted to subsequent generations (F2–F4). For a review of transgenerational effects of environmental agents, the reader is referred to Skinner *et al.* (2011).

Epigenetics refers to the biochemical changes in chromatin that lead to changes in conformation and gene expression. Epigenetic changes include DNA methylation, histone modifications, and expression of microRNAs. Although epigenetics provides the basis for imprinting of genes, the role of epigenetics is much broader (Rogers *et al.*, 2010; Grace *et al.*, 2011). There are specific stages of the life cycle during which epigenetic marks may be erased and reestablished (Sasaki and Matsui, 2008), including two periods of development during which large-scale demethylations of the genome are known to occur. One is during migration and proliferation of the primordial germ cells (between embryonic days 10.5 and 12.5 in the mouse). It is during this period that imprinted genes are demethylated, with remethylation occurring in a gender-specific manner during gametogenesis in the offspring. The other period of widespread epigenetic reprogramming occurs shortly after formation of the zygote and in the early embryo, with total genomic methylation reaching a nadir at the blastocyst stage (Hales *et al.*, 2011). This process of epigenetic reprogramming represents a putative target for environmental chemicals, and examples of environmentally mediated epigenetic changes are emerging (Skinner *et al.*, 2011; Rogers *et al.*, 2010; Perera and Herbstman, 2011).

Following fertilization, the embryo moves down the fallopian tube (oviduct) and attaches to the wall of the uterus. The *preimplantation* period comprises mainly an increase in cell number through a rapid series of cell divisions with little growth in size (*cleavage* of the zygote) and cavitation of the embryo to form a fluid-filled blastocoele. This stage, termed the *blastocyst*, consisting of about a thousand cells, may contain as few as three cells destined to give rise to the embryo proper (Markert and Petters, 1978), and these cells are within a region called the *inner cell mass*. The remainder of the blastocyst cells gives rise to extraembryonic membranes and support structures (eg, trophoblast and placenta). However, the fates of the cells in the early embryo are not completely determined at this stage. The relatively undifferentiated preimplantation embryo has great restorative (regulative) growth potential (Snow and Tam, 1979). For example, experiments by Moore *et al.* (1968) demonstrated that single cells from eight-celled rabbit embryos are capable of producing normal offspring.

Toxicity during the preimplantation period is generally thought to result in either no or slight effect on growth (because of regulative growth) or in death (through overwhelming damage or failure to implant). Preimplantation exposure to dichlorodiphenyltrichloroethane (DDT), nicotine, or methyl-methane sulfonate results in body and/or brain weight deficits and embryo lethality, but not malformations (Fabro, 1973; Fabro *et al.*, 1984). However, there are a few examples of toxic exposures during the preimplantation period leading to fetal malformations. Exposure to toxicants during a brief period (approximately six hours) immediately following fertilization has been demonstrated to result in malformed fetuses for a

few chemicals including ethylene oxide (Generoso *et al.*, 1987), ethylmethane sulfonate, ethylnitrosourea, and triethylene melamine (Generoso *et al.*, 1988). The mechanisms underlying these unexpected findings have not been elucidated but probably do not involve point mutations. Epigenetic changes were not examined, but given the time of the exposure, this is a plausible target. Treatment of pregnant mice with methylnitrosourea on days 2.5, 3.5, and 4.5 of gestation resulted in NTDs and cleft palate (Takeuchi, 1984). Cyproterone acetate and medroxyprogesterone acetate are capable of producing malformations when administered on day two of gestation (Eibs *et al.*, 1982). Rutledge and co-workers (Rutledge *et al.*, 1994) produced hind-limb and lower body duplications by treating pregnant mice with all-*trans* RA on gestation day 4.5 to 5.5, at which time the embryos are at the late blastocyst and proamniotic stages. Because of the rapid mitoses occurring during the preimplantation period, chemicals affecting DNA synthesis or integrity, or those affecting microtubule assembly, would be expected to be particularly toxic.

Following implantation, the embryo undergoes *gastrulation*. Gastrulation is the process of formation of the three primary germ layers—the *ectoderm*, *mesoderm*, and *endoderm*. During gastrulation, cells migrate through a midline structure called the *primitive streak*, and their movements set up basic morphogenetic fields in the embryo (Smith *et al.*, 1994). A prelude to *organogenesis*, the period of gastrulation is highly susceptible to teratogenesis. It is common for teratogens administered during gastrulation to produce malformations of the eye, brain, and face. These malformations are indicative of damage to the anterior *neural plate*, one of the regions defined by the cellular movements of gastrulation.

The formation of the neural plate in the ectoderm marks the onset of organogenesis, during which the rudiments of most bodily structures are established. This is a period of heightened susceptibility to malformations and extends from approximately the third to the eighth weeks of gestation in humans. Within this short period, the embryo undergoes rapid and dramatic changes. At three weeks of gestation, the human conceptus is in most ways indistinguishable from other mammalian and indeed other vertebrate embryos, consisting of only a few cell types in a trilaminar arrangement. By eight weeks, the conceptus, which can now be termed a fetus, has a form clearly recognizable as human. The rapid changes during organogenesis require cell proliferation and migration, cell–cell interactions, and morphogenetic tissue remodeling. These processes can be exemplified by the ontogeny of the *neural crest* cells. These cells originate at the border of the neural plate and migrate to form a wide variety of structures throughout the embryo. For example, neural crest cells derived from segments of the hindbrain (*rhombomeres*) migrate to form bone and connective tissues in the head (Krumlauf, 1993; Vaglia and Hall, 1999; Trainor and Krumlauf, 2001), while other neural crest cells form diverse structures including melanocytes, enteric ganglia, and adrenal medulla, and contribute to the cardiac outflow tract.

Within organogenesis, there are periods of peak susceptibility for each forming structure. This is nicely illustrated by the work of Shenefelt (1972), who studied the malformations caused by carefully timed doses of RA in pregnant hamsters. The incidences of some of the defects seen after RA administration at different times in pregnancy are shown in Fig. 10-2. The peak incidence of each malformation coincides with the timing of key developmental events in the affected structure. Thus, the specification of developmental fields for the eyes is established quite early, and microphthalmia has an early critical period. Establishment of rudiments of the long bones of the limbs occurs later, as does susceptibility to shortened limbs. The palate has two separate peaks of susceptibility, the first

corresponding to the early establishment of the palatal folds and the second to the later events leading to palatal closure. Notice also that the total incidence of malformations is lower prior to organogenesis but increases to 100% by gestation day 7 $\frac{3}{4}$. The processes underlying the development of normal structures are incompletely understood but involve a number of key events. A given toxicant may affect one or several developmental events, so the pattern of sensitivity of a structure can change depending on the nature of the toxic insult. Cleft palate can be induced in mouse fetuses following maternal exposure to methanol as early as day five of gestation, with a peak sensitivity at day seven and little or no sensitivity after day nine (Rogers and Mole, 1997). In contrast, the typical peak critical period for induction of cleft palate in the mouse for most teratogens is between gestation days 11 and 13, during the stages of growth, elevation, and fusion of the palatal shelves. In a large series of experiments in naval medical research institute (NMRI) mice, the day of peak sensitivity to the induction of cleft palate was day 11 for 2,3,7,8-tetrachlorodibenzodioxin (TCDD), day 12 for 2,4,5-trichlorophenoxyacetic acid, and day 13 for dexamethasone (Neubert *et al.*, 1973). Detection of unexpected critical periods like the early one for induction of cleft palate by methanol can provide clues to normal developmental processes not presently understood.

The end of organogenesis marks the beginning of the *fetal period* (from day ~57 to birth in humans), characterized primarily by tissue differentiation, growth, and physiological maturation. This is not to say that formation of the organs is complete, but rather that almost all organs are present and grossly recognizable. Further development of organs proceeds during the fetal period to attain requisite functionality prior to birth, including fine structural morphogenesis (eg, neural outgrowth and synaptogenesis, branching morphogenesis of the bronchial tree and renal cortical tubules) as well as biochemical maturation (eg, induction of tissue-specific enzymes and structural proteins). One of the latest organogenetic events is closure of the urethral groove in the male, which occurs at about gestation day 90. Failure of this event produces hypospadias, a ventral clefting of the penis.

Exposure during the fetal period is most likely to result in effects on growth and functional maturation. Functional anomalies of the central nervous system and reproductive organs—including behavioral, cognitive, and motor deficits as well as decreases in fertility—are among the possible adverse outcomes. These manifestations are not apparent prenatally and may require careful postnatal observation and testing. Such postnatal functional manifestations can be sensitive indicators of in utero toxicity, and reviews of postnatal functional deficits of the central nervous system (Rodier *et al.*, 1994; Miodovnik, 2011), immune system (Holladay and Luster, 1994; Dietert, 2008), and heart, lung, and kidneys (Lau and Kavlock, 1994) are available. Major structural alterations can occur during the fetal period, but these generally result from deformations (disruption of previously normal structures) rather than malformations. The extremities may be affected by amniotic bands, wrapping of the umbilical cord, or vascular disruptions, leading to loss of distal structures. Over the past two decades, the concept of “developmental programming” has emerged, in which the developmental environment is thought to influence the metabolic parameters of the offspring that will persist throughout life and may affect lifelong risk of disease (for review, see McMillen and Robinson, 2005; Gluckman *et al.*, 2011; Barouki *et al.*, 2012). Much of the work on fetal programming has focused on the role of maternal nutrition, and there is a paucity of data concerning the long-term effects of chemical exposure during the fetal and early postnatal periods (Lau and Rogers, 2004). Some effects could require years to become apparent (such as those noted

Figure 10-2. Critical periods of sensitivity for induction of various defects by retinoic acid in the hamster. Incidence of defects estimates for the embryo/fetal LD_{50} maternal dosage. Note in the top panel that fewer malformations are induced on days five to six, prior to organogenesis, indicating that during this period embryos for the most part either die or recover. Likelihood of malformation increases rapidly during gastrulation and reaches 100% during organogenesis. Peak incidence for each defect is enumerated and reflect timing of critical events in the development of each structure. (Modified from Shenefelt (1972), with permission.)

above for DES), and others may even result in the premature onset of senescence and/or organ failure late in life. In rats, prenatal exposure to high dosages of ethanol during the second half of pregnancy shortens life span of the offspring, by about 20 weeks in females and 2.5 to seven weeks in males (Abel *et al.*, 1987).

Dose–Response Patterns and the Threshold Concept

The major effects of prenatal exposure, observed in fetuses near term in developmental toxicity studies, are growth retardation, malformations, and embryo death. The relationships among these effects are complex and vary with the chemical, the time of exposure, and the dose. For some chemicals these endpoints may represent a continuum of increasing toxicity, with low dosages producing growth

retardation and increasing dosages producing malformations and then death. Malformations and/or death can occur without a concomitant effect on intrauterine growth, but this is unusual. Likewise, growth retardation and embryo lethality can occur without malformations. Chemicals producing the latter pattern of response would be considered embryotoxic or embryolethal but not teratogenic (unless it was established that death was due to a structural malformation). Effects on function in viable fetuses will usually require postnatal assessment. Transition to postnatal life is a rigorous test in itself, and severe functional effects may manifest as neonatal mortality.

Another key element of the dose–response relationship is the shape of the dose–response curve at low exposure levels. Because of the high restorative growth potential of the mammalian embryo, cellular homeostatic mechanisms, and maternal metabolic defenses, mammalian developmental toxicity has generally been considered to

be a threshold phenomenon. Assumption of a threshold means that there is a maternal dosage below which no increase in an adverse outcome is elicited. Daston (1993) summarized two approaches for establishing the existence of a threshold. The first, exemplified by a large teratology study on 2,4,5-T (Nelson and Holson, 1978), suggests that no study is adequately capable of evaluating the dose–response at low response rates (eg, in this study it was calculated that 805 litters per dose would be necessary to detect a 5% increase in resorptions of embryos). The second approach is to determine whether a threshold exists for the molecular mechanism responsible for the observed effect. Although relatively few mechanisms of abnormal development have been thoroughly studied, it is clear that cellular and embryonic repair mechanisms and dose-dependent kinetics both support the plausibility of a mechanistic threshold. Lack of a threshold implies that exposure to any amount of a toxic chemical, even one molecule, has the potential to cause developmental toxicity. Hypothetically, a point mutation in a critical gene could be induced by a single hit or single molecule, leading to a deleterious change in a gene product and consequent abnormal development. This, of course, carries the large assumption that the molecule could traverse the maternal system and the placenta and enter a critical progenitor cell in the embryo. An effect on a single cell might result in abnormal development at the zygote (one-cell) stage, the blastocyst stage (when only a few cells in the inner cell mass are embryo progenitors), or during organogenesis, when organ rudiments may consist of only a few cells.

An apparent threshold for developmental toxicity based at least in part on cellular homeostatic mechanisms is demonstrated in studies of mechanisms underlying the teratogenicity of 5-fluorouracil (Shuey *et al.*, 1994; see also “Safety Assessment” later in this chapter). This chemical inhibits the enzyme thymidylate synthetase (TS), thus interfering with DNA synthesis and cell proliferation. Significant embryonal TS inhibition is evident at maternal dosages an order of magnitude lower than those required to produce malformations and about fivefold below those affecting fetal growth (Fig. 10-3). The lack of developmental toxicity despite significant TS inhibition probably reflects an ability of the embryo to compensate for imbalances in cellular nucleotide pool sizes.

For human health risk assessment, it is also important to consider the distinction between individual thresholds and population thresholds. There is wide variability in the human population, and a threshold for a population can be defined as the threshold of the most sensitive individual in the population (Gaylor *et al.*, 1988). Indeed, even though the biological target of a developmental toxicant may exhibit a threshold, background factors such as health status or concomitant exposures may render some individuals already at or even beyond the threshold for failure of that biological process. Any further toxic impact on that process, even one molecule, would theoretically increase risk. The concept of thresholds of adversity for reproductive toxicants has recently been reviewed by Piersma *et al.* (2011a).

MECHANISMS AND PATHOGENESIS OF DEVELOPMENTAL TOXICITY

The term *mechanisms* is used here to refer to cellular events that initiate a process leading to abnormal development. *Pathogenesis* comprises the cell-, tissue-, and organ-level sequelae that ultimately lead to abnormality. Mechanisms of teratogenesis listed by Wilson (1977) include mutations, chromosomal breaks, altered mitosis, altered nucleic acid integrity or function, diminished supplies of precursors or substrates, decreased energy supplies, altered

Figure 10-3. Relationship between inhibition of embryonal thymidylate synthetase and adverse fetal outcome following maternal 5-fluorouracil (5-FU) administration on gestation day 14 in the rat. 5-FU inhibits embryonal TS activity at low dosages, with most of the inhibition occurring below 20 mg/kg. Fetal weight is affected at 20 mg/kg and above, whereas incidence of anomalies increases only at 30 mg/kg and above. Anomalies include edema, skull dysmorphology, orbital hemorrhage, wavy ribs, cleft palate, brachygnathia and hindlimb defects. (Based on Shuey *et al.* (1994) and unpublished observations.)

membrane characteristics, osmolar imbalance, and enzyme inhibition. Although these cellular insults are not unique to development, they may relatively quickly trigger unique pathogenic responses in the embryo, such as reduced cell proliferation, cell death, altered cell–cell interactions, reduced biosynthesis, inhibition of morphogenetic movements, or mechanical disruption of developing structures.

Elucidating the mechanism(s) and pathogenesis of chemically induced developmental toxicity can be extremely challenging. Cyclophosphamide (CP), a chemotherapeutic and immunosuppressive drug, has been studied for its teratogenicity for 50 years, and is a good case study (Mirkes, 1985a; Ozolins, 2010). Because of its use as an immunosuppressive drug to treat lupus, at least nine cases of teratogenesis induced by inadvertent exposure to CP during early pregnancy have been recorded (Paladini *et al.*, 2004). Efforts to understand the teratogenicity of this drug provide an example of approaches to understanding metabolic activation, teratogenic mechanisms, and pathogenesis. Much of this and other mechanistic work was made possible by the advent of rodent whole embryo culture (WEC), which involves removing rodent or rabbit embryos from the uterus at the beginning of organogenesis and growing them in serum-containing culture media (New, 1978; Sadler and Warner, 1984; Ellis-Hutchings and Carney, 2010; Robinson *et al.*, 2012a,b,c,d; Lee *et al.*, 2012). Embryos will grow normally for about 48 hours, completing most of organogenesis. The ability to grow embryos in isolation allows direct exposure, manipulation, and observation. The use of rodent WEC as a screening system for developmental toxicity will be discussed later in this chapter.

Using WEC, Fantel *et al.* (1979) and Sanyal *et al.* (1979) showed that hepatic S9 fractions and cofactors were required to elicit abnormal development by CP, demonstrating that it must be metabolically activated to be teratogenic. Activation of CP was inhibited by metyrapone or carbon monoxide, indicating involvement of P450 monooxygenases. Of the CP metabolites, 4-hydroxycyclophosphamide (4OHCP) and aldophosphamide (AP) are unstable. A stable derivative of 4OHCP, 4-hydroperoxy-cyclophosphamide (4OOHCP) was

tested *in vivo* (Hales, 1982) and in WEC (Mirkes, 1987). In the latter study, the morphology of the treated embryos was indistinguishable from that of embryos cultured with CP plus an activating system. Spontaneous conversion of 4OOHCP to 4OHCP and then to phosphoramidate mustard (PM) and acrolein (AC) occurs rapidly, and these further metabolites, as well as 4-ketocyclophosphamide (4-ketoCP) and carboxyphosphamide (CaP), have also been studied for their teratogenicity. It appears that 4OHCP is not teratogenic (Hales, 1983) and toxicity elicited by 4-ketoCP is dissimilar to that of activated CP (Mirkes *et al.*, 1981). Subsequent work centered on the two remaining metabolites, PM and AC. Mirkes *et al.* (1981) demonstrated that the effects of PM on cultured rat embryos were indistinguishable from those of activated CP. Hales (1982) administered CP, PM, or AC to gestation day 13 rat embryos by intra-embryonic injection. CP and AC caused hydrocephaly, open eyes, cleft palate, micrognathia, omphalocele, and tail and limb defects, whereas PM produced only hydrocephaly and tail and limb defects. Thus, both PM and AC appear to be teratogenic metabolites of CP.

What are the cell and molecular targets of activated CP, and what is the nature of the interactions? Experiments with (^3H)CP showed that approximately 87% of bound radioactivity was associated with protein, 5% with DNA, and 8% with RNA (Mirkes, 1985b). Using alkaline elution, it was demonstrated that CP and PM produce single-strand DNA breaks and DNA-DNA and DNA-protein cross-linking. To determine whether DNA cross-linking is essential for teratogenicity, a monofunctional derivative of PM, capable of producing single-strand breaks but not cross-links in DNA, was tested. Although higher concentrations were needed, this derivative produced the same spectrum of effects as PM (Mirkes *et al.*, 1985). Later, Little and Mirkes (1990) showed that 4-hydroperoxydechlorocyclophosphamide, a CP analog that yields AC and a nonalkylating derivative of PM, did not produce DNA damage when embryos were exposed in serum-containing medium, but this analog retained teratogenicity. Using radiolabeled CP, they further found that AC preferentially binds to protein and shows high incorporation into the yolk sac, whereas PM binds preferentially to DNA. Hales (1989) showed that PM and AC have strikingly different effects on limb buds in culture. These results indicate that PM and AC have different targets in the embryo and that PM is responsible for CP-induced DNA damage.

How do chemical insults at the cell and molecular level translate to a birth defect? To illustrate pathogenesis, we will consider cell cycle perturbations and cell death, continuing our example of CP. Cell death plays a critical role in normal morphogenesis. The term *programmed cell death* refers to a specific type of cell death, *apoptosis*, under genetic control in the embryo (Lavin and Watters, 1993). Apoptosis is necessary for sculpting the digits from the hand plate, for instance (Hernandez-Martinez and Covarrubias, 2011), and for assuring appropriate functional connections between the central nervous system and distal structures. Cell proliferation is obviously essential for development. Cells within the primitive streak of the gastrula-stage rat embryo have the shortest known cell cycle time of any mammalian cell, three to 3.5 hours (MacAuley *et al.*, 1993). Cell proliferation rates change both spatially and temporally during ontogenesis, as can be demonstrated by examining the proportion of cells in S-phase over time in various tissues during mid-to late gestation (Fig. 10-4). There is a delicate balance between cell proliferation, cell differentiation, and apoptosis in the embryo, and one molecular mechanism discussed above, DNA damage, might lead to the cell cycle perturbations and cell death induced in specific cell populations by CP.

Maternal CP treatment on gestation day 10 in the rat causes an S-phase cell cycle block as well as widespread cell death in the

Figure 10-4. Normal developmental changes in cell cycle distributions in erythroblasts, embryo (minus the liver after GD 13), and fetal liver. Percentages of cells in: • G₀/G₁; ■ S; and ▲ G₂/M are shown for rat embryos between gestation days 10 and 19 (note changing x-axis range). The proportion of cells in S-phase generally reflects proliferation rate, which decreases with developmental stage in the embryo and erythroblasts. The percentage of S-phase cells in the fetal liver remains fairly high and constant until near term, when a growth spurt occurs. (From Elstein *et al.* (1993), with permission.)

embryo (Fig. 10-5). In agreement with the S-phase cell cycle block, cell death is observed in areas of rapid cell proliferation (Chernoff *et al.*, 1989; Francis *et al.*, 1990). Similar embryonal cell cycle blockage and cell death were observed using activated CP in WEC (Little and Mirkes, 1992). The embryonal neuroepithelium is quite sensitive to CP-induced cell death, whereas the heart is resistant; differences in cell cycle length may, in part, underlie this differential sensitivity. The neuroepithelium of the day 10 rat embryo has a cell cycle time of approximately 9.5 hours, whereas the cell cycle length in the heart was estimated to be 13.4 hours. This difference is due to a longer G₀/G₁ phase in the heart cells compared to the neuroepithelium (Mirkes *et al.*, 1989). Damage to DNA by PM occurs predominantly during S-phase (Little and Mirkes, 1992), which constitutes a relatively smaller proportion of the cell cycle in the heart than in the neuroepithelium. Damage to DNA can inhibit

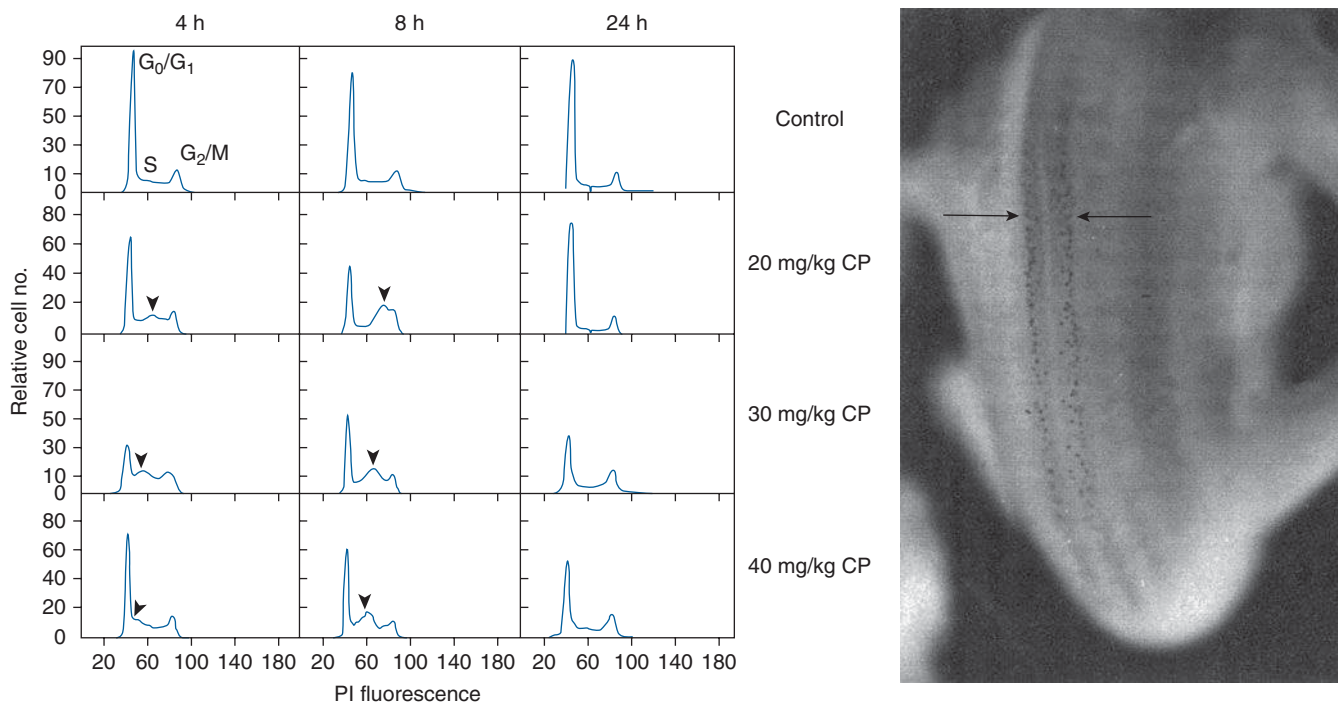

Figure 10-5. Maternal cyclophosphamide (CP) administration on gestation day 10 in CD-1 mice produces perturbations of the embryonal cell cycle and cell death in areas of rapid proliferation. *Left:* Cells are inhibited from progressing through the S (DNA synthetic) phase of the cell cycle, indicated by the abnormal population of cells (arrowheads) accumulating at progressively earlier stages of S phase four and eight hours after increasing maternal CP dosages. The upper panels show the normal GD 10-11 distributions, with the G₀/G₁, S, and G₂/M peaks identified in the upper left panel. By 24 hours postdosing, cell cycle distributions have returned to normal at 20 mg/kg, but remain abnormal at higher dosages. *Right:* Nile blue sulfate staining of a mouse embryo 24 hours after maternal CP dosing shows cell death (stippling along either side of the midline, arrows) in the neural tube, one of the most sensitive target sites for CP. (Adapted from Chernoff *et al.* (1989), with permission.)

cell cycle progression at the G₁/S transition, through the S phase, and at the G₂/M transition. If DNA damage is repaired, the cell cycle can return to normal, but if damage is too extensive or cell cycle arrest too long, apoptosis may be triggered. An increasing number of genes are being identified that play a role in apoptosis (White, 1993; Jurisicova and Acton, 2004). The *p53* gene, which functions as a tumor suppressor, can promote apoptosis or growth arrest. Apoptosis occurring during normal development does not require this gene, as *p53*-deficient embryos develop normally. However, *p53* may be critical for induction of growth arrest or apoptosis in response to DNA damage. The incidence of benzo[*a*]pyrene-induced resorptions were increased 2.6-fold and 3.6-fold, respectively, in heterozygous and homozygous *p53*-deficient embryos compared to normal homozygous controls (Nicol *et al.*, 1995). Growth factors and some cytokines (eg, IL-3, IL-6) can prevent *p53*-dependent apoptosis. Expression of *c-myc* produces continued DNA synthesis, which may precipitate apoptosis in the face of DNA damage. *Bcl-2* functions as a repressor of apoptosis and functions in conjunction with *Bax*, a homolog that dimerizes with itself or with *Bcl-2*. *Bax* homodimers favor cell death whereas *Bcl-2*/*Bax* heterodimers inhibit cell death (Oltvai and Korsmeyer, 1994; Boumela *et al.*, 2011).

A common approach to test a hypothesized mechanism of teratogenesis is to administer chemicals expected to ameliorate or exacerbate the effects based on the putative mechanism of action. Several investigators have taken this approach in studying CP. Because bioactivation of CP was hypothesized to be necessary for its teratogenicity, Gomes-Carneiro *et al.* (2003) treated rats with β -ionone, a known inhibitor of CYP2B1, the enzyme that activates CP, four minutes prior to CP injection. Severity and incidence of teratogenicity was reduced, supporting the hypothesis. Conversely,

licorice extract, an upregulator of CYP2B1 expression, exacerbated the teratogenicity of CP (Park *et al.*, 2011). Ginseng extract inhibits the CP-detoxifying enzyme CYP3A, and treatment with this extract also enhances the teratogenicity of CP. One hypothesis for the downstream teratogenic mechanism of the active CP metabolite(s) involves alkylation of cellular macromolecules. Thiol-containing molecules protect against alkylating agents, and the thiol molecules cysteine, glutathione, and Na-2-mercaptoethane sulfonate have been shown to ameliorate CP teratogenicity (Ashby *et al.*, 1976; Hales, 1981; Slott and Hales, 1986). However, these studies did not measure the degree of CP alkylation. Treatment with the antioxidant ascorbic acid attenuates CP-induced embryonic death and chromosomal damage (Kola *et al.*, 1989), whereas another antioxidant, butylated hydroxyanisole, protects against CP teratogenicity in rats (Kang *et al.*, 2003) and mice (Kim *et al.*, 2003).

Advances in the Molecular Basis of Dysmorphogenesis

Rapid advances in molecular biology, genomics, proteomics, and bioinformatics have brought new understanding of mechanisms of normal and abnormal development. A key approach, targeted gene disruption by homologous recombination (gene “knockout”; KO), has been used to study the function of many gene products in developing and adult animals. An example is the retinoic acid receptor (RAR) family of nuclear ligand-inducible transcription factors that bind RA and 9-*cis* RA. Chambon and colleagues have produced mice lacking several of these receptors either singly or as multiple KOs. Single-receptor isoform mutants were often unaffected, suggesting functional redundancy, whereas double mutants presented with widespread malformations of the skeleton and viscera (Lohnes *et al.*, 1994;

Mendelsohn *et al.*, 1994). The compound RAR γ -RAR β null mouse exhibits syndactyly, indicating that RA plays a role in interdigital cell death (Dupe *et al.*, 1999). The retinoid receptors (RXR α , β , and γ) bind 9-*cis* RA exclusively, and it is now understood that RAR/RXR heterodimers are involved in RA signaling via transcriptional control in the embryo (Mark *et al.*, 2006, 2009). A wide variety of spontaneous and genetically altered mouse strains are commercially available, and expanding compendia of mutants of other animals including zebrafish and frogs are available.

Synthetic antisense oligonucleotides have been used to ablate gene products in a temporally and spatially restricted manner. In this technique, 15 to 25 mer oligonucleotides are synthesized that are complimentary to the mRNA to be disrupted (Helene *et al.*, 1990). These probes can enter embryonal cells, and hybridization with cellular mRNA causes disruption of native message, such that gene function can be turned off at specific times. The proto-oncogenes Wnt-1 and Wnt-3a have been implicated in the development of the midbrain and hindbrain. Augustine *et al.* (1993) attenuated Wnt-1 expression using antisense oligonucleotide inhibition in mouse embryos developing in culture. Exposure during neurulation produced mid- and hindbrain malformations similar to those seen in Wnt-1 null mutant mice, as well as cardiac anomalies not observed in Wnt-1 KO mice created by homologous recombination. Antisense attenuation of Wnt-3a caused anomalies of the forebrain, midbrain, and spinal cord. Simultaneously attenuating both Wnt-1 and Wnt-3a targeted all brain regions and worsened the effect on the spinal cord, suggesting that these genes may serve a complementary function in the development of the central nervous system. Morpholino antisense oligonucleotides contain nucleic acid analogs that resist breakdown, and morpholinos have been used extensively in the study of zebrafish biology (Bedell *et al.*, 2011). RNA interference is a more recent gene knockdown technique, exploiting the discovery of the RNA interference pathway. Small interference (Si)RNA, plasmid-, and virus-encoded small RNAs can be used to down regulate the expression of specific genes posttranscriptionally (Shan, 2010).

Gain of gene function can also be studied by engineering genetic constructs with an inducible promoter attached to the gene of interest. Ectopic gene expression can be made ubiquitous or site-specific depending on the choice of promoter to drive expression. Ectopic expression of the *Hoxa-7* gene induced in mouse embryos by attaching it to the chicken β -actin promoter resulted in a phenotype exhibiting multiple craniofacial and cervical vertebral malformations (Balling *et al.*, 1989; Kessel *et al.*, 1990). Transient overexpression of specific genes can be accomplished by adding extra copies using adenoviral transduction. In proof-of-concept, Hartig and Hunter (1998) injected an adenoviral vector containing either the bacterial β -galactosidase or green fluorescent protein reporter gene under the control of the human cytomegalovirus early gene promoter into the intra-amniotic space of neurulation-stage mouse embryos and achieved intense gene expression in the neuroepithelium.

Advances in gene targeting and transgenic strategies now allow modification of gene expression at specific points in development and in specific cell types. Conditional KOs or knockins, inducible gene expression and other techniques are being used to study the effects of specific gene products on development in great detail (Mikkola and Orkin, 2005).

Reporter transgenes contain a gene with a readily detectable product fused downstream of a selected regulatory region. The *Escherichia coli lacZ* (β -galactosidase) gene is commonly used for this purpose. Cell lineage studies can be carried out by fusing *lacZ* to a constitutive regulatory sequence and introducing the construct into a somatic cell early in ontogenesis. The reporter gene will then be expressed in and mark all progeny of the transfected

cell. This method has been used to study postimplantation development in the mouse embryo (Sanes *et al.*, 1986), although intracellular injection of fluorescent dyes has also proven highly reliable for cell lineage studies (eg, Smith *et al.*, 1994). The pattern of expression of a particular gene of interest can be discriminated by fusing upstream regulatory elements of the gene to *lacZ*, which will then be transcribed under control of those upstream elements (Zakany *et al.*, 1990). RA can activate hox genes in vitro, and some hox genes have multiple RA response elements (RAREs). Evidence that RA-induced malformations in mouse embryos are related to changes in hox expression was first provided by staining of hox*lacZ* transgenic embryos (Marshall *et al.*, 1992). Within a few hours of RA treatment, hoxb-1 expression extended anteriorly, suggesting that hox genes could be direct targets of RA induction. Regions of altered hox expression could be manifest as abnormal cell fate and morphogenesis (Marshall *et al.*, 1996; Collins and Mao, 1999).

Reporter genes have recently been used to great advantage to study gene expression in zebrafish (eg, Saydmohammed *et al.*, 2011).

The use of modern biological techniques to elucidate a mechanism of developmental toxicity is exemplified by work on the perfluorinated alkyl acids (PFAAs), perfluorooctanoic acid (PFOA), and perfluorooctane sulfonate (PFOS). The PFAAs are a family of industrial chemicals that has been widely used as surfactants, hydrophobic and oleophobic treatments, and nonstick coatings. These chemicals are highly resistant to environmental degradation and are therefore persistent in the environment. Studies in experimental animals have demonstrated that developmental toxicity is among the most sensitive toxic effects of these chemicals (Lau *et al.*, 2004). Treatment of pregnant mice with either PFOS or PFOA resulted in dose-related increases in mortality of offspring in the first few days of life. Although the toxic endpoint is similar for PFOA and PFOS, their mechanisms of action may be different. PFAAs have varied affinity for the peroxisome proliferator-activated receptor alpha (PPAR α), and activation of PPAR α is a putative mechanism of action for the developmental toxicity of these chemicals. To explore the role of PPAR α activation in the developmental toxicity of PFOA and PFOS, Abbott and colleagues tested the developmental toxicity of these chemicals in PPAR α null mice. Exposure of pregnant wild-type and PPAR α KO mice to PFOA revealed that neonatal mortality, the signature effect of developmental exposure to PFOA, was dependent on PPAR α expression. The survival of PPAR null offspring was not affected by maternal PFOA exposure, whereas survival of wild-type offspring was significantly reduced (Abbott *et al.*, 2007). Somewhat surprisingly, when the same experiments were carried out with PFOS exposure, the PPAR α null offsprings were not protected from neonatal mortality (Abbott *et al.*, 2009). Studies were undertaken to compare the ability of PFAAs to activate mouse and human PPAR α in COS-1 cells (a commonly used cell line derived from kidney cells of the African green monkey) transiently transfected with either a mouse or human PPAR α -luciferase reporter plasmid, such that activation of the receptor caused light emission that could be quantified on a luminometer (Wolf *et al.*, 2008). In agreement with the KO mouse studies, PFOA activated both the mouse and human PPAR α at lower concentrations than did PFOS. Further evidence that PPAR α activation was required for PFOA but not PFOS developmental toxicity came from studies of gene expression changes induced in fetal tissues by maternal treatment with PFOA or PFOS (Rosen *et al.*, 2007, 2009). Although both PFOA and PFOS activated PPAR α downstream genes, PFOA did so in a more consistent and robust fashion. This could also be seen in livers from adult mice treated with PFOA or PFOS. Although PPAR α KO mice did not upregulate certain PPAR α -related genes

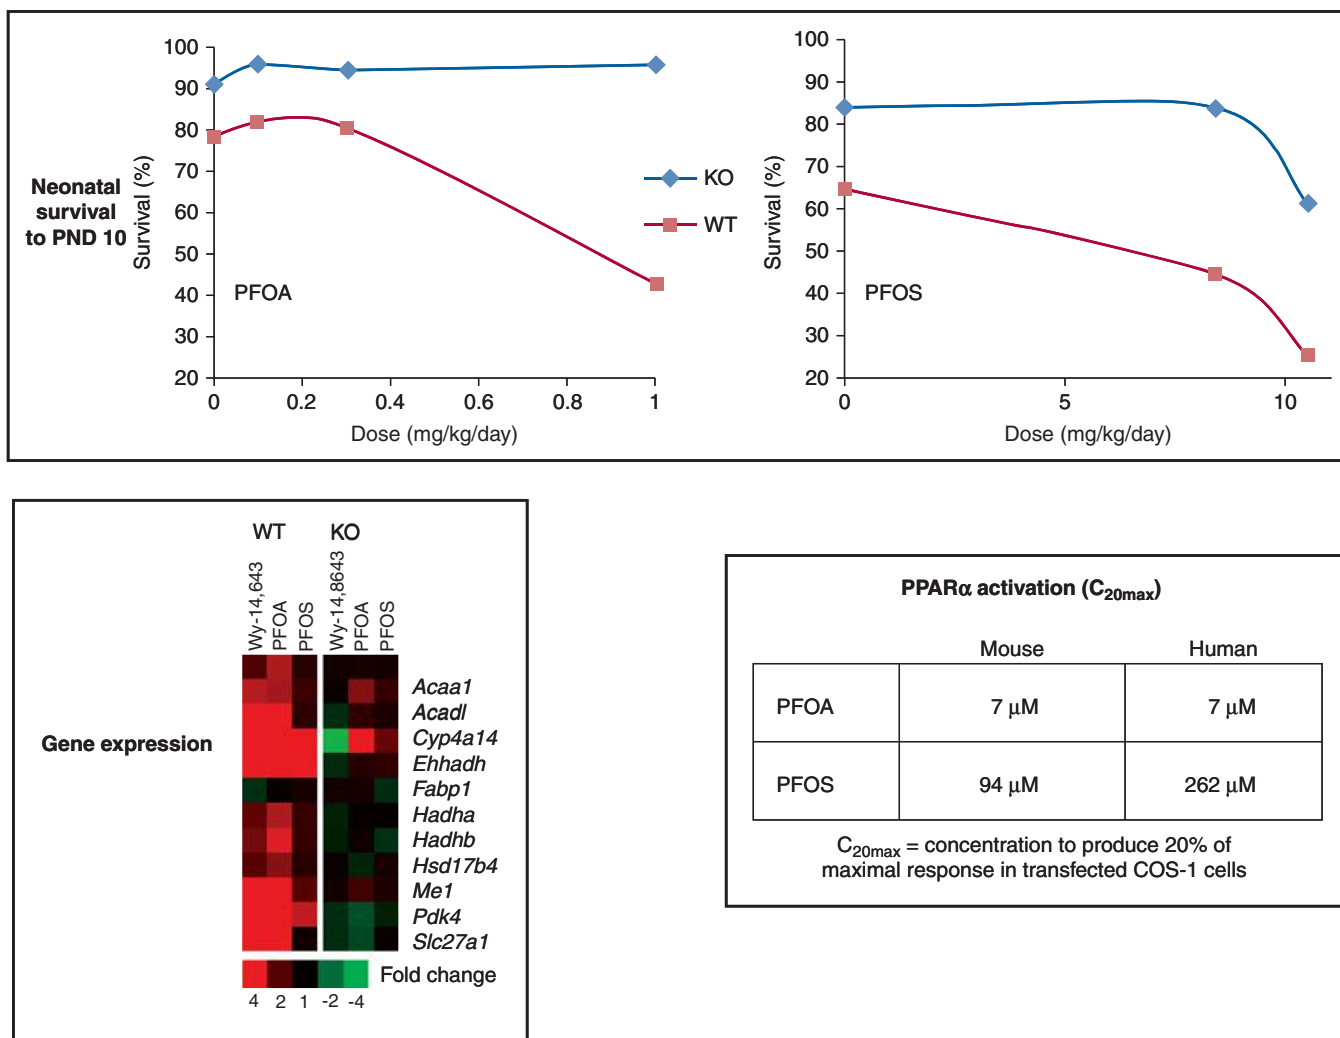

Figure 10-6. Role of the peroxisome proliferator-activated receptor- α (PPAR α) in the developmental toxicity of perfluorooctanoic acid (PFOA) and perfluorooctanesulfonate (PFOS). *Top:* PFOA or PFOS was administered to pregnant wild-type (WT) and PPAR α knockout (KO) mice throughout gestation. Neonatal survival of offspring of KO mice was not affected by PFOA, whereas survival of offspring of WT mice was greatly reduced at the high dose (left, data from Abbott *et al.*, 2007). In contrast, neonatal survival was affected by PFOS in both KO and WT offspring (right, data from Abbott *et al.*, 2009). These results suggest that PPAR α plays a role in the toxicity of PFOA but not PFOS. *Bottom left:* Adult male KO or WT mice were treated for seven days with PFOA, PFOS, or the known PPAR α agonist Wy-14,643. Expression of genes known to be upregulated by PPAR α activation was increased by treatment with PFOA or Wy-14,643, but not PFOS (data from Rosen *et al.*, 2010; figure courtesy of Dr. Mitchell Rosen). *Bottom right:* PFOA or PFOS treatment of COS-1 cells transiently transfected with either a mouse or a human PPAR α -luciferase reporter plasmid demonstrated that PFOA is a much stronger agonist of PPAR α than is PFOS (data from Wolf *et al.*, 2008).

upon PFOA or PFOS treatment, the expression of other genes was changed by exposure to either of these PFAAs, indicating that the influence of either PFOA or PFOS may extend beyond activation of PPAR α (Rosen *et al.*, 2010). This elegant set of experiments on the developmental toxicity of the PFAAs is illustrated in Fig. 10-6. It remains to be determined which of the pathways downstream of PPAR α are involved in the developmental toxicity of PFOA, and which non-PPAR α -related pathways might be perturbed by PFOS.

PHARMACOKINETICS AND METABOLISM IN PREGNANCY

The manner in which chemicals are absorbed during pregnancy and the extent to and form in which they reach the conceptus are important determinants of whether the chemical can impact development. The maternal, placental, and embryonic compartments are distinct but interacting systems that undergo profound changes

during the course of pregnancy. Maternal adaptations to pregnancy include changes in hepatic metabolism, the gastrointestinal tract, cardiovascular system, excretory system, and the respiratory system (Hyttén, 1984; Krauer, 1987; Mattison *et al.*, 1991). Although these changes are necessary to support the growing needs of the conceptus in terms of energy supply and waste elimination, they can have significant impact on the uptake, distribution, metabolism, and elimination of xenobiotics. For example, decreases in intestinal motility and increases in gastric emptying time result in longer retention of ingested chemicals in the upper gastrointestinal tract. Cardiac output in humans increases by 30% to 40% by the 27th week of pregnancy, whereas blood volume increases and plasma proteins and peripheral vascular resistance decrease. The relative increase in blood volume over red cell volume leads to borderline anemia and a generalized edema with a 70% elevation of extracellular space. Thus, the volume of distribution of a chemical and the amount bound by plasma proteins may change considerably during pregnancy. Renal blood flow and glomerular filtration rate also

increase during pregnancy. Respiratory changes including increases in tidal volume, minute ventilation, and minute O_2 uptake can result in increased pulmonary distribution of gases and decreased time to reach alveolar steady state.

In addition to changes in maternal physiology, limited evidence suggests that relative rates of drug metabolizing enzymes also change during pregnancy (Juchau, 1981; Juchau and Faustman-Watts, 1983). Maternal hepatic P450 enzymes increase during pregnancy in humans, whereas decreased hepatic monooxygenase activity has been observed during pregnancy in rats, attributed to decreased enzyme levels and competitive inhibition by circulating steroids (Neims, 1976). Another factor that contributes to lower monooxygenase activity may be changes in inducibility—pregnant rats appear to be less responsive to induction of hepatic monooxygenases by phenobarbital (but not 3-methylcholanthrene) than are nonpregnant females (Guenther and Mannering, 1977). Maternal handling of a chemical bears considerable weight in determining the extent of embryotoxicity. In one of the few studies of its type, Kimmel and Young (1983) found that a linear combination of the 45-minute and the 24-hour maternal blood concentrations was able to predict the litter response rate for pregnant rats dosed with 500 mg/kg sodium salicylate on gestation day 11. These two kinetic parameters probably reflect the influence of peak drug concentration as well as cumulative area under the concentration–time curve on developmental toxicity.

The placenta plays a central role in influencing embryonic exposure by helping to regulate blood flow, by offering a transport barrier, and by metabolizing chemicals (Slikker and Miller, 1994). Functionally, the placenta acts as a lipid membrane that permits bidirectional transfer of substances between maternal and fetal compartments. The extent of transfer depends on three major elements: the type of placentation, the physicochemical properties of the chemical, and rates of placental metabolism. Although there are marked species differences in types of placentas, orientation of blood vessels, and numbers of exchanging layers (Carney *et al.*, 2004), these do not seem to play a dominant role in placental transfer of most chemicals. It is important to note that virtually any substance present in the maternal plasma will cross the placenta to some extent. The passage of most drugs across the placenta seems to occur by simple passive diffusion, the rate of which is proportional to the diffusion constant of the drug, the concentration gradient between the maternal and embryonic plasma, the area of exchange, and the inverse of the membrane thickness (Nau, 1992). Important modifying factors to the rate and extent of transfer include lipid solubility, molecular weight, protein binding, the type of transfer (passive diffusion, facilitated or active transport), the degree of ionization, and placental metabolism. Weak acids appear to be rapidly transferred across the placenta during early pregnancy in rats and mice, due in part to the pH gradient between the maternal and embryonic plasma which can trap ionized forms of the drug in the slightly more basic embryonic compartment (Nau and Scott, 1986). In humans and rabbits, maternal serum is either similar to or slightly higher in pH than is the yolk sac fluid (Carney *et al.*, 2005).

Quantifying the form, amount, and timing of chemical delivery to the embryonic compartment in the context of concurrent developmental processes is an important component of understanding mechanisms of embryotoxicity and species differences in embryonic sensitivity (Nau, 1986). The small size of the conceptus during organogenesis and the fact that the embryo is changing at a rapid rate during this period make assessment of toxicokinetics difficult. Nevertheless, there has been considerable progress in this area (Nau and Scott, 1987; Clark, 1993; Corley *et al.*, 2003; Corley, 2010). Increasingly sensitive analytical methods are now providing

evidence to challenge the historical view, particularly for cytochrome P450-dependent monooxygenases, that the early embryo has low metabolic capabilities (Juchau *et al.*, 1992). Using the WEC system, Juchau and co-workers demonstrated that the rat conceptus was able to generate sufficient amounts of metabolites of the proteratogen 2-acetylaminofluorene (2-AAF) to induce dysmorphogenesis, and that the proximate toxicant, the 7-hydroxy metabolite, was different from the metabolite responsible for 2-AAF mutagenesis and carcinogenesis. Prior exposure of the dams to 3-methylcholanthrene increased the sensitivity of the cultured embryos to 2-AAF, thus demonstrating the inducibility of at least some cytochromes in the conceptus. These investigators later showed that embryos could further metabolize the 7-hydroxy metabolite to an even more toxic catechol. No previous induction was necessary for this activation step, demonstrating the presence of constitutive metabolizing enzymes in the embryo. Although the rates of metabolism for these activation steps may be low relative to the maternal liver, they occur close to the target site of the embryo or even within it, and thus are significant in terms of inducing embryotoxicity.

Physiologically based pharmacokinetic models provide the framework to integrate what is known about physiological changes during pregnancy, both within and between species, with aspects of drug metabolism and embryonic development into a quantitative description of the events. Olanoff and Anderson (1980) described the kinetics of the antibiotic tetracycline in the pregnant rat and her fetuses. Importantly, growth of the fetus and placenta was incorporated into the model. Gabrielson and co-workers (Gabrielson and Paalkow, 1983; Gabrielson and Larsson, 1990) were among the early investigators to develop physiologically based models of pregnancy, and others (Fisher *et al.*, 1989; O'Flaherty *et al.*, 1992; Clark *et al.*, 1993; Luecke *et al.*, 1994, 1997; Young, 1998) have added to their comprehensiveness. The Fisher model included growth of several maternal tissues during pregnancy. The model of O'Flaherty and co-workers describes the entire period of gestation, and includes the uterus, mammary tissue, maternal fat, kidney, liver, other well-perfused maternal tissues, embryo/fetal tissues and yolk sac, and chorioallantoic placenta. It takes into account the growth of various compartments during pregnancy (including the embryo itself), as well as changes in blood flow and the stage-dependent pH gradients between maternal and embryonic plasma. Transfer across the placenta is diffusion limited in this model. The utility of the model was evaluated using 5,5-dimethylloxazolidine-2,4-dione (DMO), a weak acid that is not appreciably bound to plasma proteins and is eliminated by excretion in the urine. The model demonstrated that the whole body disposition of DMO, including distribution to the embryo, can be accounted for solely on the basis of its pKa and of the pH and volumes of body fluid spaces. Differences between the disposition of DMO by the pregnant mouse and rat are consistent simply with differences in fluid pH. Luecke and co-workers developed quantitative models for human embryofetal growth for use in models of human pregnancy (Luecke *et al.*, 1994, 1997, 1999).

Chemical-specific PBPK models for pregnancy can range from simple to complex, with the degree of complexity often limited by lack of knowledge about mechanism of action or limited biological or chemical-specific data. One example is the solvent 2-methoxyethanol found to be embryotoxic and teratogenic in all species tested to date. The proximate teratogen appears to be the metabolite 2-methoxyacetic acid (2-MAA). A physiologically based pharmacokinetic model has been developed for the pregnant mouse (Terry *et al.*, 1995). Pharmacokinetics and tissue partition coefficients for 2-MAA were determined at different stages of embryonal development, and various models were tested based on

the alternative hypotheses involving (1) blood flow limited delivery of 2-MAA to model compartments, (2) pH trapping of ionized 2-MAA within compartments, (3) active transport of 2-MAA into compartments, and (4) reversible binding of 2-MAA within compartments. Although the blood flow limited model best predicted gestation day eight dosimetry, the active transport models better described dosimetry on gestation days 11 and 13. Using published data on biotransformation of 2-methoxyethanol to ethylene glycol and 2-MAA in rats, Hays *et al.* (2000) adapted the pregnant mouse PBPK model to the pregnant rat and successfully predicted tissue levels of 2-MAA following oral or intravenous administration of 2-methoxyethanol. The next step was to extrapolate this model to the inhalation route of exposure, and to model both rats and humans (Gargas *et al.*, 2000). The extrapolation of the model enabled predictions of the exposures needed for pregnant women to reach blood concentrations (C_{\max} or area under the curve [AUC]) equivalent to those in pregnant rats exposed to the no observed adverse effect level (NOAEL) or lowest observed adverse effect level (LOAEL) for developmental toxicity. The body of work on PBPK modeling of 2-methoxyethanol is exemplary of the power of these techniques for extrapolating across dose, developmental stage, route, and species. For a review of chemical-specific PBPK models, see Corley *et al.* (2003) and Corley (2010).

RELATIONSHIPS BETWEEN MATERNAL AND DEVELOPMENTAL TOXICITY

Although all developmental toxicity must ultimately result from an insult to the conceptus at the cellular level, in mammals the insult may occur through a direct effect on the embryo/

fetus, indirectly through toxicity of the agent to the mother and/or the placenta, or a combination of direct and indirect effects. Maternal physiological conditions capable of adversely affecting the developing organism include decreased uterine blood flow, maternal anemia, under or malnutrition, toxemia, altered organ function, autoimmune states, diabetes, electrolyte or acid–base disturbances, decreased milk quantity or quality, elevated stress hormones, and abnormal behavior (Chernoff *et al.*, 1989; Daston, 1994). Induction or exacerbation of such maternal conditions by chemicals and the degree to which they manifest in abnormal development are dependent on maternal genetic background, age, parity, size, nutrition, disease, stress, and other health parameters and exposures (DeSesso, 1987; Chernoff *et al.*, 1989; Rogers *et al.*, 2005). These relationships are depicted in Fig. 10-7. In this section, we will discuss maternal conditions known to adversely affect the conceptus, as well as examples of xenobiotics whose developmental toxicity results completely or in large part from maternal or placental toxicity.

The distinction between direct and indirect developmental toxicity is important for interpreting results of standard developmental toxicity bioassays in pregnant animals, as the highest dosage levels in these experiments are deliberately chosen to produce measurable maternal toxicity (eg, decreased food or water intake, weight loss, clinical signs). However, maternal toxicity defined only by such overt manifestations provides little insight into the toxic actions of a xenobiotic. When developmental toxicity is observed only in the presence of maternal toxicity, the developmental effects may be indirect; however, an understanding of the physiological changes underlying the observed maternal toxicity and elucidation of their association with developmental

Figure 10-7. Interrelationships between maternal susceptibility factors, metabolism, induction of maternal physiological or functional alterations, placental transfer and toxicity, and developmental toxicity. A developmental toxicant can cause abnormal development through any one or a combination of these pathways. Maternal susceptibility factors determine the predisposition of the mother to respond to a toxic insult, and the maternal effects listed can adversely affect the developing conceptus. Most chemicals traverse the placenta in some form, and the placenta can also be a target for toxicity. In most cases, developmental toxicity is probably mediated through a combination of these pathways.

effects is needed before one can begin to address the relevance of the observations to human safety assessment. Many known human developmental toxicants, including ethanol and cocaine, adversely affect the embryo/fetus predominately at maternally toxic levels, and part of their developmental toxicity may be ascribed to secondary effects of maternal physiological disturbances. For example, the nutritional status of alcoholics is generally poor, and effects on the conceptus may be exacerbated by effects of alcohol on placental transfer of nutrients. Chronic alcohol abuse alters maternal folate and zinc metabolism, which may play a role in the induction of fetal alcohol syndrome (Dreosti, 1993). Carney (2010) has constructed a useful decision tree for interpreting developmental toxicity observed concomitantly with maternal toxicity (Fig. 10-8).

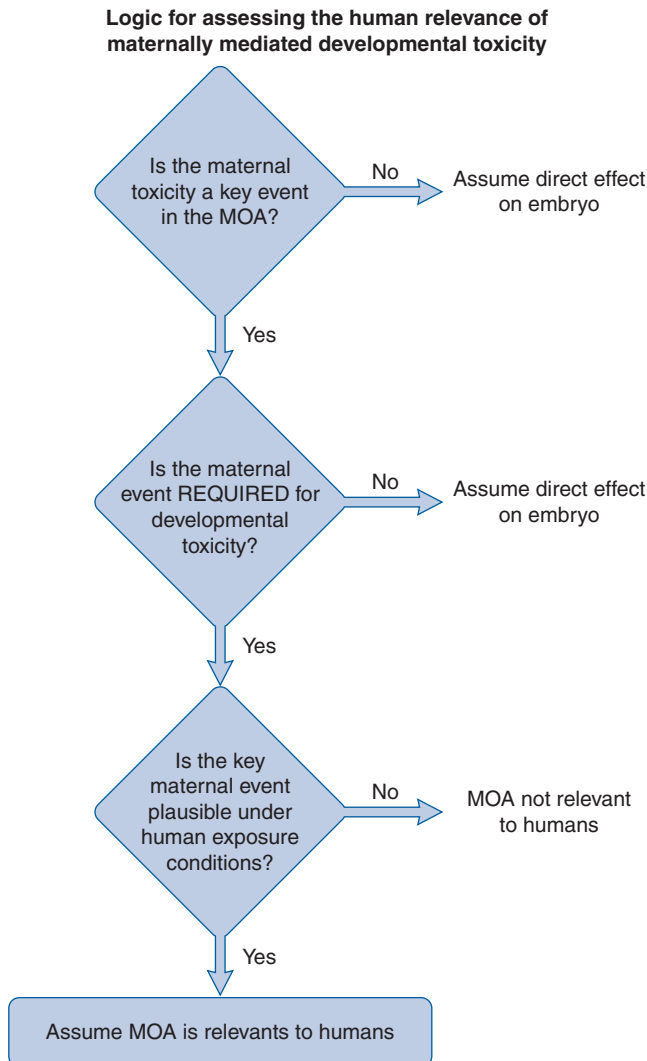

Figure 10-8. Assessing the relevance to humans of a maternally mediated mode of action. Flow chart for considering whether a maternally mediated mode of action (MOA) in animal studies is relevant to humans. When developmental toxicity is observed only at maternally toxic dosages, the MOA for developmental toxicity may be direct or indirect (secondary to the maternal toxicity). Maternally mediated developmental toxicity is relevant to humans if expected human exposure conditions could plausibly trigger that MOA (redrawn from Carney, 2010, with permission). Knowledge of the MOA for developmental toxicity, which will likely require investigation beyond the dose–response study, is a prerequisite for using this approach.

MATERNAL FACTORS AFFECTING DEVELOPMENT

Genetics

The genetic makeup of the pregnant female has been well documented as a determinant of developmental outcome in both humans and animals. The incidence of cleft lip and/or palate [CL(P)], which occurs more frequently in whites than in blacks, has been investigated in offspring of interracial couples in the United States (Khoury *et al.*, 1983). Offspring of white mothers had a higher incidence of CL(P) than offspring of black mothers after correcting for paternal race, whereas offspring of white fathers did not have a higher incidence of CL(P) than offspring of black fathers after correcting for maternal race.

Among experimental animals, two related mouse strains, A/J and CL/Fr, produced spontaneous CL(P) at 8% to 10% and 18% to 26% frequencies, respectively. The incidence of CL(P) in offspring depends on the genotype of the mother rather than that of the embryo (Juriloff and Fraser, 1980). The response to vitamin A of mouse embryos heterozygous for the curly-tail mutation also depends on the genotype of the mother (Seller *et al.*, 1983). The teratogenicity of phenytoin has been compared in several inbred strains of mice. The susceptibility of offspring of crosses between susceptible A/J mice and resistant C57BL/6J mice was determined by the maternal, but not the embryonic genome (Hansen and Hodes, 1983).

Recent work has begun to identify genes associated with differential susceptibility of mouse strains to valproic acid (Finnell *et al.*, 1997; Craig *et al.*, 2000; Bennett *et al.*, 2000; Faiella *et al.*, 2000; Okada *et al.*, 2004, 2005). A recent study utilized inbred C57BL/6J (B6) and DBA/2J (D2) mice to examine the role of maternal genotype in sensitivity to valproic acid teratogenesis (Downing *et al.*, 2010). The B6 mice are more susceptible to valproate-induced digital and vertebral malformations, whereas D2 mice are more susceptible to rib malformations. In a reciprocal cross experiment between B6 and D2 mice, genetically identical F1 offspring responded in a manner consistent with the genotype of the mother: F1 carried in a B6 mother exhibited more vertebral and digital malformations, whereas F1 carried in a D2 mother exhibited more rib malformations. Such maternal effects clearly demonstrate the importance of the maternal milieu in determining outcomes of developmental exposures.

Disease

A number of maternal diseases can exert untoward effects on the conceptus. Chronic hypertension is a risk factor for the development of preeclampsia, eclampsia, and toxemia of pregnancy, and hypertension is a leading cause of pregnancy-associated maternal deaths. Uncontrolled maternal diabetes mellitus is a significant cause of prenatal morbidity. Certain maternal infections can adversely affect the conceptus (eg, rubella virus, discussed earlier), either through indirect disease-related maternal alterations or direct transplacental infection. Cytomegalovirus infection is associated with fetal death, microcephaly, mental retardation, blindness, and deafness (MacDonald and Tobin, 1978) and maternal infection with *Toxoplasma gondii* is known to induce hydrocephaly and chorioretinitis in infants (Alford *et al.*, 1974). One factor common to many disease states is hyperthermia. Hyperthermia is a potent experimental animal teratogen (Edwards, 1986), and there is a body of evidence associating maternal febrile illness during the first trimester of pregnancy with birth defects in humans, most notably

malformations of the central nervous system (Warkany, 1986; Milunsky *et al.*, 1992; Edwards, 2006).

Nutrition

A wide spectrum of dietary insufficiencies ranging from protein-calorie malnutrition to deficiencies of vitamins, trace elements, and/or enzyme cofactors is known to adversely affect pregnancy (Keen *et al.*, 1993). Among the most significant findings related to human nutrition and pregnancy outcome in recent years are results of studies in which pregnant women at risk for having infants with NTDs were supplemented with folate (Wald, 1993; Czeizel, 2011). The largest and most convincing study is the Medical Research Council (MRC) Vitamin Study, in which supplementation with 4 mg of folic acid reduced NTD recurrence by over 70% (MRC, 1991; Bendich, 1993). Results of these studies prompted the US CDC to recommend folate supplementation for women of childbearing age and folate supplementation of some foodstuffs. In 1996, FDA mandated enrichment of cereal grain products with folate by 1998. One study has demonstrated more than a doubling of mean serum folate concentrations across all sex and age groups since then (Dietrich *et al.*, 2005). Yet, in the same population, less than 10% of women of childbearing age reached the recommended erythrocyte folate concentration of greater than 906 nmol/L that has been shown to be associated with a reduction in the risk of NTDs. The CDC (2004) estimated that the number of NTD-affected pregnancies in the United States declined from 4000 in 1995–1996 to 3000 in 1999–2000. Although this survey indicates partial success of the folate fortification program, women capable of becoming pregnant were urged to continue to follow the US Public Health Service recommendation to consume 400 μ g folate daily. Mills and Signore (2004) compared the rates of antenatal detection of NTDs in the United States (incomplete ascertainment and underprediction of NTDs) and Canada (more complete antenatal ascertainment) and determined that the studies that best identify cases of NTDs show that folic acid fortification is preventing around 50% of NTDs. These authors estimate that the percentage of folate-preventable NTDs in the United States is about 50% to 60%, suggesting that we may be close to achieving optimum protection. However, recent studies using multivitamins containing folate have achieved even better results (Czeizel *et al.*, 2011).

Stress

Diverse forms of maternal toxicity may have in common the induction of a physiological stress response. Thus, understanding the potential effects of maternal stress on development may help interpret developmental toxicity observed in experimental animals at maternally toxic dosages. Various forms of physical stress have been applied to pregnant animals in attempts to isolate the developmental effects of stress. Subjecting pregnant rats or mice to noise stress throughout gestation can produce developmental toxicity (Kimmel *et al.*, 1976; Nawrot *et al.*, 1980, 1981). Restraint stress produces increased fetal death in rats (Euker and Riegler, 1973) and cleft palate (Barlow *et al.*, 1975), fused and supernumerary ribs, and encephaloceles in mice (Beyer and Chernoff, 1986).

Objective data on effects of stress in humans are difficult to obtain. Nevertheless, studies investigating the relationship of maternal stress and pregnancy outcome have indicated a positive correlation between stress and adverse developmental effects, including low birth weight and adverse mental health outcomes in offspring

(Stott, 1973; Gorsuch and Key, 1974; Beydoun and Saftlas, 2008; Entringer *et al.*, 2010; Dunkel Schetter and Tanner, 2012).

Placental Toxicity

The placenta is the interface between the mother and the conceptus, providing attachment, an immune interface, nutrition, gas exchange, and waste removal. The placenta also produces peptide and steroid hormones critical to the maintenance of pregnancy and the regulation of fetal and maternal metabolism. The placenta can also metabolize or store xenobiotics. Placental toxicity may compromise these functions and produce or contribute to adverse effects on the conceptus. Slikker and Miller (1994) listed 46 substances known to be toxic to the yolk sac or chorioallantoic placenta, including metals such as cadmium (Cd), arsenic or mercury, cigarette smoke, ethanol, cocaine, endotoxin, and sodium salicylate. Cd is among the best studied of these, and it appears that the developmental toxicity of Cd during mid-to-late gestation involves both placental toxicity (necrosis, reduced blood flow) and inhibition of nutrient transport across the placenta. Maternal injection of Cd during late gestation resulted in fetal death in rats, despite little cadmium entering the fetus (Parizek, 1964; Levin and Miller, 1980). Fetal deaths occurred concomitantly with reduced uteroplacental blood flow within 10 hours (Levin and Miller, 1980). The authors' conclusion that fetal death was caused by placental toxicity was supported by experiments in which fetuses were directly injected with Cd. Despite fetal Cd burdens almost 10-fold higher than those following maternal administration, only a slight increase in fetal death was observed.

Cd is a transition metal similar in physicochemical properties to the essential metal zinc (Zn). Cd interferes with Zn transfer across the placenta (Ahokas *et al.*, 1980; Sorrell and Graziano, 1990), possibly via metallothionein (MT), a metal-binding protein induced in the placenta by Cd. Because of its high affinity for Zn, MT may sequester Zn in the placenta, impeding transfer to the conceptus (induction of maternal hepatic MT by Cd or other agents can also induce fetal Zn deficiency, as discussed below). Cadmium inhibits Zn uptake by human placental microvesicles (Page *et al.*, 1992) suggesting that Cd may also compete directly with Zn for membrane transport. Cadmium may also competitively inhibit other Zn-dependent processes in the placenta. Coadministration of Zn ameliorates the developmental toxicity of administered Cd, further indicating that interference of Cd with Zn metabolism is a key to its developmental toxicity (Ferm and Carpenter, 1967, 1968; Daston, 1982).

In the last decade it has become evident that the placenta can undergo adaptive responses to the intrauterine milieu that can influence the metabolic “programming” of the fetus (Myatt, 2006). Adverse intrauterine conditions including hypoxia and nutritional deficiencies can lead to alterations in placental structure and function, including altered expression or activity of transporters and receptors. Placental morphometry has been proposed as a biomarker of fetal programming (Thornburg *et al.*, 2010). One role of the placenta that is key for fetal programming is as a regulator of glucocorticoid transfer between the mother and her fetus(es) (Seckl and Holmes, 2007). The enzyme 11 β -hydroxysteroid dehydrogenase-2 (11 β -HSD2) inactivates glucocorticoids; its activity in the placenta protects the fetus from over exposure to maternal stress hormone. In experimental animals, lowering the activity of 11 β -HSD2 by nutritional deficiency or gene ablation leads to lower birth weight, and causes increases in adult blood pressure, circulating glucose concentrations and hypothalamic-pituitary-adrenal axis activity in

offspring. In humans, babies with lower birth weight have higher levels of plasma cortisol throughout life.

Maternal Toxicity

A retrospective analysis of relationships between maternal toxicity and specific types of prenatal effects found species-specific associations. Yet, among rat, rabbit, and hamster studies, 22% failed to show any developmental toxicity in the presence of significant maternal toxicity (Khera, 1984, 1985). In a study designed to test the potential of maternal toxicity to affect development, Kavlock *et al.* (1985) administered 10 structurally unrelated compounds to pregnant mice at maternotoxic dosages. Developmental effects were agent-specific, ranging from complete resorption to lack of effect. An exception was an increased incidence of supernumerary ribs (ribs on the first lumbar vertebra), which occurred with seven of the 10 compounds. Chernoff *et al.* (1990) dosed pregnant rats for 10 days with a series of compounds chosen because they exhibited little or no developmental toxicity in previous studies. When these compounds were administered at higher dosages producing maternal toxicity (weight loss or a low incidence of death), varied adverse developmental outcomes were noted, including increased intrauterine death (two compounds), decreased fetal weight (two compounds), supernumerary ribs (two compounds), and enlarged renal pelvises (two compounds). Two of the compounds produced no developmental toxicity despite substantial maternal toxicity. These diverse developmental responses led the authors to conclude that maternal toxicity characterized by weight loss or mortality was not associated with any consistent syndrome of developmental effects in the rat.

There have been a number of studies relating specific forms of maternal toxicity to developmental toxicity, including those in which the test chemical caused maternal effects that exacerbated the developmental toxicity of the chemical, and instances in which developmental toxicity was thought to be secondary to maternal effects. However, clearly delineating the relative role(s) of indirect maternal and direct embryo/fetal toxicity is difficult. What follows are examples of the kinds of experiments that may allow one to do so.

Acetazolamide inhibits carbonic anhydrase and is teratogenic in mice (Hirsch and Scott, 1983). Although maternal weight loss was not correlated with malformation frequency, maternal hypercapnia potentiated the teratogenicity of acetazolamide. In C57Bl/6J mice, maternal hypercapnia alone resulted in right forelimb ectrodactyly, the characteristic malformation induced by acetazolamide. Correction of maternal acidosis failed to reduce developmental toxicity, suggesting that the primary teratogenic factor was elevated maternal plasma CO₂ tension (Weaver and Scott, 1984a,b).

Diflunisal, an analgesic and anti-inflammatory drug, causes axial skeletal defects in rabbits. Developmentally toxic dosages resulted in severe maternal anemia (hematocrit = 20%–24% vs 37% in controls) and depletion of erythrocyte ATP levels (Clark *et al.*, 1984). Teratogenicity, anemia, and ATP depletion were unique to the rabbit among the species studied. A single dose of diflunisal on day five of gestation produced maternal anemia that lasted through day 15. Concentration of the drug in the embryo was less than 5% of the peak maternal blood level, and diflunisal was cleared from maternal blood before day nine, the critical day for induction of similar axial skeletal defects by hypoxia. Thus, the teratogenicity of diflunisal in the rabbit was probably due to hypoxia resulting from maternal anemia.

Phenytoin, an anticonvulsant, can affect maternal folate metabolism in experimental animals, and these alterations may play a

role in the teratogenicity of this drug (Hansen and Billings, 1985). Further, maternal heart rates were monitored on gestation day 10 after administration to susceptible A/J mice and resistant C57Bl/6J mice (Watkinson and Millicovsky, 1983). Heart rates were depressed by phenytoin in a dose-related manner in the A/J mice but not in C57Bl/6J mice. A mechanism of teratogenesis was proposed relating depressed maternal heart rate and embryonic hypoxia. Supporting studies have demonstrated that hyperoxia reduced the teratogenicity of phenytoin in mice (Millicovsky and Johnston, 1981).

Reduced uterine blood flow has been proposed as a mechanism of teratogenicity caused by hydroxyurea, which produces elevated systolic blood pressure, altered heart rate, decreased cardiac output, severely decreased uterine blood flow, and increased vascular resistance in pregnant rabbits (Millicovsky *et al.*, 1981). Embryos exhibited craniofacial and pericardial hemorrhages immediately after treatment (Millicovsky and DeSesso, 1980a) and identical embryopathies were achieved by clamping the uterine vessels of pregnant rabbits for 10 minutes (Millicovsky and DeSesso, 1980b).

MT synthesis is induced by a wide variety of chemical and physical agents including metals, alcohols, urethane, endotoxin, alkylating agents, hyper- or hypothermia, and ionizing radiation (Daston, 1994). MT synthesis is also induced by endogenous mediators such as glucocorticoids and certain of the cytokines (Klaassen and Lehman-McKeeman, 1989). A mechanism common to the developmental toxicity of these diverse agents may be Zn deficiency of the conceptus secondary to induction of maternal MT. Induction of synthesis can produce hepatic MT concentrations over an order of magnitude higher than normal, leading to substantial sequestration of circulating Zn in maternal liver, lowered plasma Zn concentrations, and reduced Zn availability to the conceptus. Embryofetal zinc deficiency secondary to maternal hepatic MT induction has been demonstrated for diverse chemicals including valproic acid (Keen *et al.*, 1989), 6-mercaptopurine (Amemiya *et al.*, 1985, 1989), urethane (Daston *et al.*, 1991), ethanol, and α -hederin (Taubeneck *et al.*, 1994). In a study combining data for many of these compounds, Taubeneck and co-workers (1994) found a strong positive relationship between maternal hepatic MT induction and maternal hepatic ⁶⁵Zn retention, and a negative relationship between maternal MT induction and ⁶⁵Zn distribution to the litter. This is an example of a maternally mediated mechanism of exacerbating or directly causing developmental toxicity, one that is applicable to diverse maternal insults and for which direct exposure of the conceptus to the causative agent is not required.

Maternal ethanol exposure and the induction of FASD represent an excellent example of the interplay of indirect (maternally mediated) and direct toxic mechanisms of action (Fig. 10-9). Alcoholic mothers exhibit tolerance to alcohol such that their blood alcohol levels can be quite high and no doubt exert multiple direct effects on the embryo, including induction of cell death, altered neural crest cell migration, mitochondrial dysfunction, and effects on membrane integrity. At the same time, effects of chronic alcohol exposure on the mother include MT induction and secondary embryofetal zinc deficiency, as described above. Zn deficiency is teratogenic and exerts multiple adverse effects on the developing conceptus as shown in Fig. 10-9. Additional maternal effects that may exacerbate teratogenicity include hypoferrremia, reduced circulating folate, reduced circulating vitamin A, and hypercupremia. Genetic polymorphisms in both the mother and the fetus likely play roles in manifestation of FASD as well, as evidenced by studies in humans and in animal models (Warren and Li, 2005). Thus, despite literally thousands of epidemiological, clinical, and laboratory studies, the complex interplay of factors involved in the teratogenicity of ethanol is still being elucidated.

Figure 10-9. Alcohol-induced acute phase response and sequence of events leading to conceptual zinc deficiency. Multiple mechanisms underlie the teratogenicity of alcohol (box at upper right). Tissue damage in maternal tissues can initiate an acute phase response that includes induction of metallothionein in maternal liver, which removes available zinc from the maternal circulation, reducing availability to the conceptus. In addition to contributing to zinc deficiency in the embryo/fetus, an acute phase response can affect the metabolism of other essential nutrients, including folate, Vitamin A, iron and copper. NAP: neuroprotective octapeptide NAPVSIPQ; SAL: neurotropic nonapeptide SALLRSIPA. (Redrawn from Keen *et al.* (2010), with permission).

DEVELOPMENTAL TOXICITY OF ENDOCRINE-DISRUPTING CHEMICALS

An “endocrine disruptor” has been broadly defined as “an exogenous chemical that interferes with the production, release, transport, metabolism, binding, action, or elimination of natural hormones responsible for the maintenance of homeostasis and the regulation of developmental processes” (Kavlock *et al.*, 1996). More recently, the Endocrine Society has stated: “an endocrine-disrupting substance is a compound, either natural or synthetic, which, through environmental or inappropriate developmental exposures, alters the hormonal and homeostatic systems that enable the organism to communicate with and respond to its environment” (Diamanti-Kandarakis *et al.*, 2009). Due to the critical role of hormones in directing differentiation in many tissues, the developing organism is particularly vulnerable to fluctuations in the timing or intensity of exposure to chemicals with hormonal (or antihormonal) activity. A wide variety of chemical classes (eg, pesticides, herbicides, fungicides, plasticizers, surfactants, organometals, halogenated polyaromatic hydrocarbons, phytoestrogens) have been shown to cause developmental toxicity via at least three modes of action involving the endocrine system: (1) by acting as hormone receptor ligands; (2) by altering steroid hormone synthetic and metabolic enzymes; and (3) by perturbing hypothalamic-pituitary release of tropic hormones. Interactions with the functions of estrogens, androgens, and

thyroid hormones have been the most studied, but the underlying principles apply to other hormones as well.

Laboratory Animal Evidence

Chemicals with estrogenic activity are a well-described class of developmental toxicants based on standard criteria of causing specific malformations during critical developmental periods of relatively short duration (Schardein, 2000). Estrogens induce pleiotropic effects, acting on diverse cell types with estrogen receptors, and can display cell and organ-specific agonist and antagonist actions. The pattern of outcomes is generally similar across different estrogens. DES provides one of the most well-characterized examples of the effects of a xenoestrogen on development. Manifestations include malformations and functional alterations of the male and female reproductive tract and brain. In the CD1 mouse, effective exposures are in the range of 0.1 to 100 $\mu\text{g}/\text{kg}$ on gestation day (GD) nine to 16 (Newbold, 1995). At the higher end of the exposure range (10–100 $\mu\text{g}/\text{kg}$), total sterility of female offspring is noted, due in part to structural abnormalities of the oviduct, uterus, cervix, and vagina, and to depletion and abnormalities of ovarian follicles. In adulthood, male offspring show hypospadias, whereas females exhibit excessive vaginal keratinization and epidermoid tumors of the vagina. Vaginal adenocarcinoma is seen at dosages as low as 2.5 $\mu\text{g}/\text{kg}$ maternal body weight, and benign uterine tumors

(leiomyomas) are seen at as low as 0.1 µg/kg. In male offspring, sterility is observed at high doses, the result of retained rete testes and Mullerian duct remnants, abnormal sperm morphology and motility, cryptorchidism, abnormal reproductive tract secretions, and inflammation (Newbold, 1995). DES exposure of pregnant mice also causes obesity in female offspring (Newbold *et al.*, 2009). Other estrogenic (or antiestrogenic) developmental toxicants include estradiol (Biegel *et al.*, 1998; Cook *et al.*, 1998), ethinyl estradiol, antiestrogenic drugs such as tamoxifen and clomiphene citrate (Branham *et al.*, 1998), and pesticides and industrial chemicals such as methoxychlor (Gray *et al.*, 1989; Hall *et al.*, 1997; Amstislavsky *et al.*, 2003, 2004, 2006), *o,p*-DDT (Heinrichs *et al.*, 1971), kepone (Gellert, 1978; Guzelian, 1982), dioxins (Mably *et al.*, 1992; Gray *et al.*, 1997a,b), bisphenol A (Nagel *et al.*, 1997), and phytoestrogens such as genistein and coumestrol (Medlock *et al.*, 1995; Rozman *et al.*, 2006). Female offspring are generally more sensitive than males and altered pubertal development, reduced fertility, and reproductive tract anomalies are common findings.

Although most studies on estrogens have indicated traditional dose–response patterns, vom Saal and co-workers (vom Saal *et al.*, 1997; Nagel *et al.*, 1997) have reported that unusual dose–response patterns may occur for endocrine effects on some endpoints. In their studies, a 50% elevation in fetal serum estradiol concentration resulting from implantation of estradiol-containing Silastic capsules on days 13 to 19 of gestation in mice caused a 30% increase in adult prostate weight in male offspring, whereas higher maternal serum concentrations were associated with decreased adult prostate weight. A similar U-shaped dose–response pattern was observed for DES given on days 11 to 17 of gestation, as increased adult prostate weights were seen between 0.02 and 20 ng/kg/day, whereas 200 ng/kg/day resulted in smaller prostates. Bisphenol A (2 or 20 µg/kg/day on gestation days 11–17) also increased adult prostate weight in these mice. However, the issue is controversial, as other researchers using similar testing paradigms have not seen this pattern (eg, Cagen *et al.*, 1999). Vom Saal and colleagues (vom Saal and Hughes, 2005; Welshons *et al.*, 2006) argue that bisphenol A exerts estrogenic effects at low doses and exhibits an inverted U-shaped dose response. Naciff *et al.* (2005) assessed changes in gene expression in response to in utero exposure to three estrogen receptor agonists, 17 α -ethinyl estradiol, genistein, or bisphenol A. Expression of 50 genes was changed by all three chemicals, suggesting that these chemicals have a consistent mode of action. Further, the dose–response for these gene expression changes was monotonic, arguing against the existence of a U-shaped dose–response for these chemicals. Vandenberg and colleagues (Vandenberg *et al.*, 2012) have recently reviewed the issue of low dose effects and nonmonotonic dose–response curves for endocrine disruptors.

Antiandrogens are another class of endocrine-disrupting chemicals. Effects of developmental exposure to an antiandrogen are generally restricted to males, and include hypospadias, retained nipples, reduced testes and accessory sex gland weights, and decreased sperm production. Examples of chemicals known to affect development via an antiandrogenic mechanism include pharmaceuticals such as the androgen receptor antagonist flutamide (Imperato-McGinley *et al.*, 1992) and the 5 α -reductase inhibitor finasteride (Clark *et al.*, 1990), the fungicide vinclozolin (Gray *et al.*, 1994) and the DDT metabolite *p,p*-dichlorodiphenyldichloroethylene (DDE) (Kelce *et al.*, 1995; You *et al.*, 1998); the latter two are androgen receptor antagonists. Dibutylphthalate has been shown to induce an antiandrogen phenotype in developing rats, but the effect does not appear to be mediated by direct interaction with the androgen receptor (Mylchreest *et al.*, 1998, 1999). The critical developmental window for these effects of dibutylphthalate was

gestation days 16 to 18 in the rat (Carruthers and Foster, 2005). Dietary exposure of pregnant rats to dibutylphthalate from gestation days 12 to 19 resulted in dose-related decreases in androgen responsive gene expression and testicular testosterone content in male fetuses, and an antiandrogen phenotype in male offspring (Struve *et al.*, 2009). A similar phenotype has been observed in offspring of dibutylphthalate treated rabbits (Higuchi *et al.*, 2003). Importantly, recent studies have demonstrated that exposure of pregnant rats to mixtures of antiandrogenic chemicals can have a cumulative effect on development of the male offspring (Rider *et al.*, 2009, 2010; Hotchkiss *et al.*, 2010; Hannas *et al.*, 2011).

Hypothyroidism during pregnancy and early postnatal development causes growth retardation, cognitive deficits, delayed eye opening, hyperactivity, and auditory defects in rodents. Polychlorinated biphenyls (PCBs) may act at several sites to lower thyroid hormone levels during development and cause body weight and auditory deficits (Goldey *et al.*, 1995; Goldey and Crofton, 1998). PCBs also cause learning deficits and alter locomotor activity patterns in rodents (Eriksson *et al.*, 1991; Schantz *et al.*, 1995) and monkeys (Bowman, 1982; Schantz *et al.*, 1991). The thyroid hormone synthesis inhibitor propylthiouracil (PTU) has been used to study the effects of chemically induced hypothyroidism on development of the brain in rats (Gilbert, 2011). Administration of 1 to 3 ppm PTU in the drinking water of female rats during pregnancy and lactation produced deficits of thyroxine (T4) in the offspring, but only modest reductions in triiodothyronine (T3, the active thyroid hormone) at the high dose. Excitatory postsynaptic transmission was reduced and long-term potentiation was impaired in adult offspring despite the modest and transient effect on T3 during treatment.

Human Evidence

Despite the biological plausibility of effects demonstrated in numerous laboratory studies, the extent to which human health is being adversely impacted from exposures to environmental endocrine disruptors is unclear. It is difficult to demonstrate cause and effect relationships in epidemiological studies where the signals may be weak, the effects may be evident only long after an exposure, and the endpoints are sensitive to other factors. Reports in humans which are or may be relevant are of two types: (1) Observations of adverse effects on reproductive system development and function following exposure to chemicals with known endocrine activities that are present in medicines, contaminated food, or the workplace. These have tended to involve relatively high exposures to chemicals with known endocrine effects (eg, DES). (2) Epidemiological evidence of increasing trends in adverse reproductive and developmental outcomes having an endocrine basis. With the exception of DES, evidence is either lacking to support a definitive link to an exposure, or is variable across studies. Secular trends have been reported for cryptorchidism (Toppari *et al.*, 1996); hypospadias (Toppari *et al.*, 1996; Paulozzi *et al.*, 1997; Paulozzi, 1999); semen quality (Carlsen *et al.*, 1992; Skakkebaek and Keiding, 1994; Olsen *et al.*, 1995; Swan *et al.*, 1997; Auger *et al.*, 1995; de Mouzon *et al.*, 1996; Irvine *et al.*, 1996; Vierula *et al.*, 1996; Bujan *et al.*, 1996; Fisch and Goluboff, 1996), and testicular cancer (Toppari *et al.*, 1996). Recently, connections between environmental exposures and cryptorchidism and hypospadias (Toppari *et al.*, 2010), and early onset of puberty in girls (Mouritsen *et al.*, 2010) have been suggested.

The most convincing evidence for effects of endocrine-disrupting chemicals in humans comes from reports of neurobehavioral changes and learning deficits in children exposed to PCBs in utero or lactationally, either through their mothers' consumption

of PCB-contaminated fish (Jacobson *et al.*, 1990; Jacobson and Jacobson, 1996) or through exposure to background levels of PCBs in the United States (Rogan and Gladen, 1991) or the Netherlands (Koopman-Esseboom *et al.*, 1996). In addition, there have been two occurrences of high-level exposure to contaminated rice oil (in Japan in 1968 and in Taiwan in 1979) in which alterations in development of ectodermal tissues and delays in neurological development were seen (Hsu *et al.*, 1985; Yu *et al.*, 1991; Guo *et al.*, 1994; Schechter *et al.*, 1994). In these cases, there was coexposure to polychlorinated dibenzofurans and PCBs. The mode of action of the developmental neurotoxicity of PCBs is, however, not yet understood.

Impact on Screening and Testing Programs

The findings of altered reproductive development following early life stage exposures to endocrine-disrupting chemicals prompted revisions of traditional safety evaluation tests such as those issued by the EPA (USEPA, 1997). These include assessments of female estrous cyclicity, sperm parameters (total number, percent progressively motile and sperm morphology in both the parental and F1 generations), the age at puberty in the F1 (vaginal opening in the female, preputial separation in the males); an expanded list of organs for pathology and/or histopathology to identify and characterize effects at the target organ; as well as some triggered endpoints including anogenital distance in the F2 and primordial follicular counts in the parental and F1 generations. An important modification of prenatal developmental toxicity test guidelines aimed at improved detection of endocrine disruptors is the extension of the period of dosing to near the end of pregnancy in order to include the developmental period of urogenital tract differentiation.

MODERN SAFETY ASSESSMENT

Experience with chemicals that have the potential to induce developmental toxicity in humans indicates that laboratory animal testing, surveillance of the human population (ie, epidemiological studies), and alert clinical awareness (eg, Friedman, 2011) are all necessary to provide adequate public health protection. Laboratory animal investigations are guided by both regulatory requirements for drug or chemical marketing and the need to understand mechanisms of toxicity.

Regulatory Guidelines for In Vivo Testing

Prior to the thalidomide tragedy, safety evaluations for reproductive effects were limited in the types of chemicals evaluated and the sophistication of the endpoints. Subsequently, the FDA issued more extensive testing protocols (termed Segments I, II, and III) for application to a broader range of chemicals (USFDA, 1966). These testing protocols, with minor variations, were adopted by regulatory agencies around the world and remained similar for nearly 30 years. Several factors including the historical experience of testing thousands of chemicals, increased knowledge of basic reproductive processes, the ever-rising cost of testing, the acknowledged redundancy and overlap of required protocols, a growing divergence in study design requirements of various countries, and the expanding international presence of the pharmaceutical industry succeeded in producing new and streamlined testing protocols that have been accepted internationally (USFDA, 1994). These guidelines, the result of the International Conference of Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH), allow considerable flexibility in implementation

depending on the particular circumstances of the agent under evaluation. Rather than specify study and technical details, they rely on the investigator to meet the primary goal of detecting and bringing to light any indication of toxicity to reproduction. Key elements of the FDA Segment I, II, and III studies, the ICH protocols, and the organization for economic cooperation and development (OECD) equivalent of the FDA Segment II test are provided in Table 10-4. In each protocol, guidance is provided on species/strain selection, route of administration, number and spacing of dosage levels, exposure duration, experimental sample size, observational techniques, statistical analysis, and reporting requirements. Details are available in the original publications as well as in several reviews (eg, Manson, 1994; Claudio *et al.*, 1999; Reuter *et al.*, 2003). Variations of these protocols exist that include extensions of exposure to early or later time points in development and extensions of observations to postnatal ages with more sophisticated endpoints. For example, the Environmental Protection Agency's Developmental Neurotoxicity Protocol for the rat includes exposure from gestation day six through lactation day 10, and observation of postnatal growth, developmental landmarks of puberty (preputial separation, vaginal opening), motor activity, auditory startle, learning and memory, and neuropathology at various ages through postnatal day 60 (USEPA, 1998a,b).

In 2006, the Regulation on Registration, Evaluation, Authorization and restriction of Chemicals (REACH, 2006) was published. REACH requires that all chemicals marketed or manufactured in the European Union above one ton per year must be characterized as to their toxicity. The requirements are categorized by the annual tonnage of the chemical and are more extensive as the tonnage increases (Rovida *et al.*, 2011). Requirements for reproductive and developmental toxicity are included and are expected to be the largest user of live animals under REACH, which, although it encourages use of alternative toxicity tests to reduce animal use, does not currently deem screening tests for developmental toxicity sufficient to replace required whole animal tests (Scialli, 2008; Rovida *et al.*, 2011).

In part because of the development of new pharmaceuticals for use in children, a Workshop on Testing Strategies and Design of Juvenile Animal Studies was held in 2003 (Hurt *et al.*, 2004). Subsequently, the FDA and the European Medicines Agency (EMA) have promulgated guidelines for determining the need for and the design of nonclinical studies in support of registering such drugs (USFDA, 2006; EMA, 2008). The design of such studies is flexible and would depend in part on the intended use of the drug (eg, age range, duration of treatment, drug target). To assess the value of such tests, juvenile animal data were compiled from over 200 studies and reviewed in a workshop (Bailey and Marien, 2011). The consensus was that the survey demonstrated the value of juvenile studies for the development of safe pediatric drugs.

The general goal of regulatory studies is to identify the NOAEL, which is the highest dosage level that does not produce a significant increase in adverse effects in the offspring or juvenile animals. These NOAELs are then used in the risk assessment process to assess the likelihood of effects in humans given certain exposure conditions. A preferable alternative, the Benchmark Dose approach, is discussed below.

Multigeneration Tests

Information pertaining to developmental toxicity can also be obtained from studies in which animals are exposed to the test substance continuously over one or more generations (eg, OECD Test Guideline 416 or USEPA 870.3800). For additional information

Table 10-4

Summary of In Vivo Regulatory Protocol Guidelines for Evaluation of Developmental Toxicity

STUDY	EXPOSURE	ENDPOINTS COVERED	COMMENTS
<i>Segment I:</i> Fertility and general reproduction study	Males: 10 week prior to mating Females: 2 week prior to mating through implantation	Gamete development, fertility, pre- and postimplantation viability, parturition, lactation	Assesses reproductive capabilities of male and female following exposure over one complete spermatogenic cycle or several estrous cycles.
<i>Segment II:</i> Teratogenicity test	Implantation (or mating) through end of organogenesis (or term)	Viability and anatomy (external, visceral, skeletal) of fetuses prior to birth	Shorter exposure prevents metabolic adaptation and provides high exposure during gastrulation and organogenesis. Earlier dosing option for bioaccumulative agents or those impacting maternal nutrition. Later dosing option covers reproductive tract development.
<i>Segment III:</i> Perinatal study	Last trimester of pregnancy through lactation	Postnatal survival, growth, and external morphology	Intended to observe effects on development of major organ functional competence during the perinatal period, and thus may be relatively more sensitive to adverse effects at this time.
<i>ICH 4.1.1:</i> Fertility protocol	Males: 4 week prior to mating Females: 2 week prior to mating through implantation	Males: Reproductive organ weights and histology, sperm counts and motility Females: Viability of conceptuses at mid-pregnancy or later	Improved assessment of male reproductive endpoints; shorter treatment duration than Segment I.
<i>ICH 4.1.2:</i> Effects on prenatal and postnatal development, including maternal function	Implantation through end of lactation	Relative toxicity to pregnant versus non-pregnant female; postnatal viability, growth, development, and functional deficits (behavior, maturation, reproduction)	Similar to Segment I study.
<i>ICH 4.1.3:</i> Effects on embryo/fetal development	Implantation through end of organogenesis	Viability and morphology (external, visceral, skeletal) of fetuses prior to birth.	Similar to Segment II study. Usually conducted in two species (rodent and nonrodent).
<i>OECD 4.1.4:</i> Prenatal developmental	Implantation (or mating) through day prior to cesarean section	Viability and morphology (external, visceral, skeletal) of fetuses prior to birth.	Similar to Segment II study. Usually conducted in two species (rodent and nonrodent).

on this approach, see Chap. 20. A recent study (Piersma *et al.*, 2011b) has called into question the value of including a second generation on overall outcome of the assessment. These investigators conducted a retrospective analysis of 498 rat multigenerational studies, and found that the second-generation mating and offspring rarely provided critical information. These authors instead recommended adopting a proposed OECD extended one-generation test (Cooper, 2009; Vogel *et al.*, 2010) for risk assessment purposes. The extended one-generation test is flexible and could include a second generation if certain triggers were reached in the first generation. Others have argued that the triggers may be too lenient and will too frequently result in invoking production of the second generation (Beekhuijzen *et al.*, 2009).

Children's Health and the Food Quality Protection Act

In 1993, the National Academy of Sciences published a report entitled "Pesticides in the Diets of Infants and Children," which brought to light the fact that infants and children differ both qualitatively and quantitatively from adults in their exposure to pesticide residues in food because of different dietary composition and intake patterns and different activities (National Research Council [NRC], 1993). This report, along with the report from the International Life

Sciences Institute entitled "Similarities and Differences Between Children and Adults" (Guzelian *et al.*, 1992) provided background and impetus for passage of the Food Quality Protection Act (FQPA) of 1996. The FQPA incorporates an additional 10-fold safety factor for children, cumulative effects of toxicants acting through a common mode of action, aggregate exposure (ie, same toxicant from different sources), and endocrine disruption. The inclusion (at the discretion of the EPA) of the 10-fold factor for calculating allowable intakes for children affects most strongly the pesticide industry, whose products can appear as residues in food. The application of this safety factor is controversial in part because its opponents' claim that developmental susceptibility is already considered in other tests, such as the Segment II test for prenatal toxicity, the two-generation test, and the developmental neurotoxicity test. On the other hand, proponents applaud the measure and point to the numerous factors that may increase the exposure of infants and children to environmental toxicants and their susceptibility to harm from these exposures. Children have different diets than adults and also have activity patterns that change their exposure profile compared to adults, such as crawling on the floor or ground, putting their hands and foreign objects in their mouths, and raising dust and dirt during play. Even the level of their activity (ie, closer to the ground) can affect their exposure to some toxicants. In addition to exposure differences, children are growing and developing, which

makes them more susceptible to some types of insults. Effects of early childhood exposure, including neurobehavioral effects, obesity, diabetes, and cancer, may not be apparent until later in life. Debate continues over the approach to be used for risk assessment in consideration of infants and children.

A large prospective study on children's health in the United States, the National Children's Study (NCS) (Branum *et al.*, 2003; Needham *et al.*, 2005; Kimmel *et al.*, 2005; Landrigan and Miodovnic, 2011) was launched in 2009. For this longitudinal birth cohort, 100,000 children will be followed from before birth through 21 years of age. Among many parameters and endpoints to be assessed is exposure to environmental contaminants, including those present in breast milk. In this unique study, because the children will be followed to adulthood, the opportunity exists to assess the full range of potential adverse developmental consequences of environmental exposures. In addition to the National Children's Study, the US Environmental Protection Agency and the US National Institutes of Health support 14 Centers for Children's Environmental Health and Disease Prevention Research (Landrigan and Miodovnic, 2011).

Alternative Testing Strategies

A variety of alternative test systems have been proposed over several decades to refine, reduce, or replace the standard mammalian regulatory tests for assessing developmental toxicity. These assays are based on cell cultures, cultures of embryos *in vitro*, including those of worms, flies, frogs, fish, and mammals (Chapin *et al.*, 2008; Piersma *et al.*, 2010), and a short-term *in vivo* test (Chernoff and Kavlock, 1982). Daston (1996) has discussed the theoretical and empirical underpinnings supporting the use of a number of these systems. Yet, validation of these alternative tests was a major issue

(Neubert, 1989; Welsch, 1990). Although it was initially hoped that alternative approaches would become generally applicable to all chemicals, and help prioritize full-scale testing, this has not yet been accomplished. Given the complexity of embryogenesis and the multiple mechanisms and target sites of potential teratogens, it was perhaps unrealistic to have expected a single test, or even a small battery of tests, to accurately prescreen the activity of chemicals in general. Over the past decade, a validation study of three *in vitro* embryotoxicity assays, the rat embryo limb bud micromass assay, the mouse embryonic stem cell test (mEST), and the rat WEC test, has been carried out (Genschow *et al.*, 2000, 2002, 2004; Brown, 2002; Piersma *et al.*, 2004; Seiler *et al.*, 2004; Spielmann *et al.*, 2004). This study involved interlaboratory blind trials to validate these assays, and the approach involved the development of "prediction models," which mathematically combine assay endpoints to determine the combinations and formulations that are most predictive of mammalian *in vivo* results. More recently, the mEST and other approaches to using mouse embryonic stem cells have been further developed and tested, and the zebrafish embryo has gained prominence as a short-term test for developmental toxicity. Currently, developmental toxicity assays based on rodent WEC, mEST, and zebrafish embryos are receiving the bulk of research attention for use as teratogen screens (Fig. 10-10).

The rodent WEC has been discussed above as a tool for studies of chemical mechanism of action. For WEC, rodent or rabbit embryos are excised from the mother at an early stage of organogenesis with their yolk sacs intact and cultured for up to 48 hours (Ellis-Hutchings and Carney, 2010). During this time they continue to develop in a manner similar to *in utero* development. At the end of culture the embryos are scored for a number of growth and developmental parameters and assigned a developmental score (eg, rodents: Brown and Fabro, 1981; Van Maele-Fabro *et al.*, 1990;

Figure 10-10. Rodent whole embryos in culture, mouse embryonic stem cells, and zebrafish embryos are used as screens for developmental toxicity. *Left:* A whole gestation day eight mouse embryo removed from the uterus with intact yolk sac and ectoplacental cone, ready to be cultured for up to 48 hours. (Picture courtesy of Dr E. Sidney Hunter.) *Top right:* Mouse embryonic stem cells (cell line J1) in pluripotent state maintained on a feeder layer of mitotically inactivated mouse embryonic fibroblasts. (Picture courtesy of Dr Kelly Chandler.) *Lower right:* Zebrafish larvae at six days postfertilization (dpf). Note the transparency of the larva, facilitating observation of internal structures such as those labeled. (From Airhart *et al.* (2007), with permission.)

rabbits: Carney *et al.*, 2007). As a screen for developmental toxicity, the WEC has the advantages of using mammalian embryos and being able to divide the many embryos in a litter into different treatment groups. Disadvantages include the technical difficult and time-consuming process of excising the embryos and scoring them at the end of culture, and the cost in animals for obtaining the embryos and the rat serum used as culture medium. As an alternative or in addition to morphological scoring, effects of chemicals on gene expression in the embryos have been studied to discern common patterns (“signatures”) of transcriptomic effects (Luijten *et al.*, 2010; Robinson *et al.*, 2010, 2011a,b, 2012a,b,c,d).

The mEST uses established stem cell lines and examines the effects of test chemicals on viability and differentiation of the cells. The cells aggregate and form “embryoid bodies” when grown in hanging drop cultures. Cardiomyocyte differentiation in the cultures can be quantified by examining the cultures for beating cardiomyocytes. In a different version of the mEST, mouse embryonic stem cells are cultured to adherency in 96-well plates and test chemical applied for up to eight days (Barrier *et al.*, 2011; Chandler *et al.*, 2011). At the end of culture, cardiomyocyte differentiation is assessed by performing in-cell Westerns for cardiac myosin heavy chain and viability is assessed using a fluorescent dye technique. The mEST has the advantage of using established cell lines, therefore totally avoiding the use of live animals. It is also fairly rapid and inexpensive. A disadvantage is the limited developmental repertoire of the cells under the conditions of these tests. Human embryonic stem cell lines or induced pluripotent stem cells are also being developed for toxicity testing, with the obvious advantage of being human cells (Krtolica *et al.*, 2009; Vojnits and Bremer, 2010). However, at present these cells are less well characterized than are mouse embryonic stem cells, and they are generally less robust in culture.

Submammalian species have been used for many years in the study of normal developmental biology, and among these animal models, the African clawed frog, *Xenopus laevis* or *X. tropicalis* (Bantle, 1995; Fort *et al.*, 2000, 2004; Fort and Paul, 2002), and the zebrafish, *Danio rerio* (Frayssse *et al.*, 2006; Love *et al.*, 2004; Ton *et al.*, 2006; Yang *et al.*, 2009; Brannen *et al.*, 2010; Sipes *et al.*, 2011a,b; McCollum *et al.*, 2011; Selderslaghs *et al.*, 2012), have been used for developmental toxicology to a number of advantages. Chief among the features of these species is the rapid external development of the embryos, the large historical and recent literature on their normal development, and the availability of genetic mutants and molecular biological tools for studying these embryos. In addition, these species can be bred to produce large numbers of embryos in a relatively short period and are easy and inexpensive to maintain.

The zebrafish has gained increased usage in a number of fields including developmental biology and cancer research. These small fish exhibit a great deal of homology to higher vertebrates in their development, anatomy, physiology, and behavior. Their rapidly developing embryos are transparent, allowing visualization of internal anatomy. Chemical toxicity studies in zebrafish have been comprehensively compiled and reviewed (McCollum *et al.*, 2011). Zebrafish developmental toxicity testing can be carried out in 96-well plates, an approach used for assessment in zebrafish of the Phase I chemical library in the US Environmental Protection Agency’s ToxCast program (Padilla *et al.*, 2012). For a review of zebrafish development and use of zebrafish as a disease model, see *Birth Defects Research Part C: Embryo Today: Reviews* (2011;93(2)), an issue dedicated to this topic.

The ToxCast program at EPA (Kavlock *et al.*, 2012; <http://actor.epa.gov/actor/faces/ToxCastDB/Home.jsp>) includes hundreds of high-throughput assays directed at molecular and cellular targets of toxicity, a number of which are relevant to developmental

toxicity. Sipes *et al.* (2011a,b) have evaluated statistical associations of ToxCast assay data with the mammalian developmental toxicity data in EPA’s Toxicity Reference Database, ToxRefDB (<http://actor.epa.gov/toxrefdb/faces/Home.jsp>). A high number of associations between the rat and rabbit *in vivo* data and the ToxCast data were discerned, and species-specific predictive models based on the ToxCast assays exhibited greater than 70% balanced accuracy.

A streamlined alternate *in vivo* test using rodents for pre-screening for developmental toxicity was developed by Chernoff and Kavlock (1982), and is known as the Chernoff–Kavlock assay. Pregnant females are exposed during the period of major organogenesis to a limited number of dosage levels near those inducing maternal toxicity, and offspring are evaluated over a brief neonatal period for external malformations, growth, and viability. It has proven reliable over a large number of chemical agents and classes (Hardin *et al.*, 1987), and a regulatory testing guideline is available (USEPA, 1985).

Epidemiology

Reproductive epidemiology is the study of associations between specific exposures of the father or pregnant woman and her conceptus and the outcome of pregnancy (Chambers and Scialli, 2010). In rare situations, such as rubella, thalidomide, and isotretinoin, where a relatively high risk exists and the outcome is a rare event, formal studies may not be needed to identify causes of abnormal birth outcomes. The likelihood of linking a particular exposure with a series of case reports increases with the rarity of the defect, the rarity of the exposure in the population, a small source population, a short time span for study, and biological plausibility for the association (Khoury *et al.*, 1991). In other situations, such as those with ethanol and valproic acid, associations are sought through either a case–control or a cohort approach. Both approaches require accurate ascertainment of abnormal outcomes and exposures, and a large enough effect and study population to detect an elevated risk. Therein lies one of the difficulties for epidemiologists studying abnormal reproductive outcomes. For example, it has been estimated that the monitoring of more than one million births would have been necessary to detect a statistically significant increase in the frequency of spina bifida following the introduction of valproic acid in the United States, where the frequency of exposure was less than one in 1000 pregnancies and the risk was only a doubling over the background incidence (Khoury and Holtzman, 1987). Another challenge to epidemiologists is the high percentage of human pregnancy wastage, perhaps as much as 31% in the peri-implantation period (Wilcox *et al.*, 1988) and an additional 15% that are clinically recognized. Therefore, pregnancy failures related to a particular exposure may go undetected in the general population. Furthermore, with the availability of prenatal diagnostic procedures, some pregnancies with malformed embryos (particularly NTDs) are electively aborted. Thus, the incidence of abnormal outcomes at birth may not reflect the true rate of abnormalities, and the term prevalence, rather than incidence, is preferred when the denominator is the number of live births rather than total pregnancies.

Epidemiological studies of abnormal reproductive outcomes are usually undertaken with three objectives in mind: the first is scientific research into the causes of abnormal birth outcomes and usually involves analysis of case reports or clusters; a second aim is prevention and is targeted at broader surveillance of trends by birth defect registries around the world; and the last objective is informing the public and providing assurance. In this regard, it is informative to consider the review by Schardein (1993) of the method and year by which humans teratogens were detected.

For 23 of 28 chemicals reviewed (including nine cancer therapeutics, androgenic hormones, antithyroid drugs, aminoglycoside antibiotics, coumarin anticoagulants, DES, methylmercury, hydantoin, primidone, penicillamine, lithium, vitamin A, and RA), case reports presented the first evidence in humans. For two of these (DES and lithium), the case reports were soon followed by registries that provided confirmation, while for two others (methyl mercury and hydantoin) follow-up epidemiology studies added support. For only four chemicals, alcohol, PCBs, carbamazepine, and cocaine, did an analytical epidemiological study provide the first human evidence. Evidence for one chemical, valproic acid, was first obtained by analysis of a birth defect registry. For the 28 chemicals in that review, human evidence of developmental toxicity preceded published animal evidence in eleven instances. Cohort studies, with their prospective exposure assessment and ability to monitor both adverse and beneficial outcomes, may be the most methodologically robust approach to identifying human developmental toxicants. The lack of cohort studies demonstrating risk for pregnancy may be in part due to the difficulty in making such associations, but may also reflect the fact that use in pregnancy is not associated with increased risk for the majority of drugs (Irl and Hasford, 2000).

Assessment of the developmental toxicity of tobacco smoke has benefited greatly from the many epidemiological studies that have been carried out (see tobacco smoke under Scope of the Problem: The Human Experience). Reasons for this success include the prevalence of smoking and secondhand smoke exposure (allowing large studies), good recall of exposure, and biomarkers of exposure (eg, cotinine), and comprehensive assessment of effects in offspring. The large number of studies has allowed meta-analyses for selected effects.

Concordance of Data

There have been several reviews of the similarity of responses of laboratory mammals and humans to developmental toxicants. In general, these studies support the assumption that results from laboratory tests are predictive of potential human effects. Concordance is strongest when there are positive data from more than one test species. In a quantitative sense, the few comparisons that have been made suggest that humans tend to be more sensitive to developmental toxicants than is the most sensitive test species. Although concordance among species for chemicals reported as positive is high, often special steps must be taken retrospectively to produce an animal model that reflects the nature of outcome in humans (eg, valproic acid, Ehlers *et al.*, 1992 a,b).

Frankos (1985) reviewed data for 38 compounds having demonstrated or suspect developmental toxicity in humans; all except tobramycin, which caused otologic defects, were positive in at least one test species and 76% were positive in more than one test species. Predictiveness was highest in the mouse (85%) and rat (80%), with lower rates for rabbits (60%), and hamsters (40%). Frankos identified 165 chemicals with no evidence of human effects; only 29% were negative in all species tested while 51% were negative in more than one species. Schardein and Keller (1989) examined concordance by species and developmental manifestation for 51 potential human developmental toxicants that had adequate animal data (three human developmental toxicants did not). Thalidomide received the widest testing, with data from 19 species; 53% had data from three species, whereas 18% had data from four or five species. Across all chemicals, the most common findings in humans, rabbits, and monkeys were spontaneous abortion and fetal/neonatal death, followed by malformations and then growth retardation. In the rat, prenatal death, growth retardation, and then malformations was the typical

pattern. All species showed at least one positive response for 64% of the human developmental toxicants and, with only one exception, all of the potential human developmental toxicants showed a positive response in at least one species. Overall, the match to the human, regardless of the nature of the developmental response, was rat, 98%; mouse, 91%; hamster, 85%; monkey, 82%; and rabbit, 77%. Jelovsek *et al.* (1989) reviewed the predictiveness of animal data for 84 negative human developmental toxicants, 33 with unknown activity, 26 considered suspicious, and 32 considered positive. Variables considered included the response of each species, the number of positive and negative species, percent positive and negative species, and mutagenicity and carcinogenicity. The compounds were correctly classified 63% to 91% of the time based on animal data, depending upon how the suspect and unknown human toxicants were considered. The various models had a sensitivity of 62% to 75%, a positive predictive value of 75% to 100%, and a negative predictive value of 64% to 91%. A summary comparison of rodent and rabbit results for 22 human developmental toxicants has recently been compiled by Daston and Knudsen (2010) (Table 10-5).

Table 10-5

Developmental Toxicity Findings in Rodents and Rabbits for Known Human Developmental Toxicants

CHEMICAL	RODENT	RABBIT	HUMAN
Cyclophosphamide	+	+	+
Diazepam	+		+
Diethylstilbestrol	+	+	+
Phenytoin/trimethadione	+	+	+
Ethanol	+		+
Lithium	+/-		+
Methylmercury	+		+
13- <i>cis</i> -Retinoic acid	+	+	+
Testosterone	+	+	+
Thalidomide	-	+	+
Valproic acid	+	+	+
Warfarin	+		+
Fumonisin B ₁	+	-	+
Methimazole	+/-		+
Busufan	+		+
Enalapril/captopril	+		+
Polychlorinated biphenyls	+/-		+
Cocaine	+/-		+
Misoprostol	+	-	+
Penicillamine	+		+
Tetracycline	-		+
Toluene	+		+

+ indicates developmental toxicity in that species; - indicates negative findings; +/- indicates an equivocal response. Blank spaces indicate chemical not tested in that species. The type of positive finding is not necessarily the same in all species.

SOURCE: Adapted from Daston and Knudsen (2010), with permission.

The extrapolation of animal test data to predict human risk of developmental toxicity follows two basic directions, one for drugs where exposure is voluntary and usually to high dosages, the other for environmental chemicals where exposure is generally involuntary and to low levels. For drugs, a use-in-pregnancy rating has been utilized (USFDA, 1979). In this system the letters A, B, C, D, and X are used to classify the evidence that a chemical poses a risk to the human conceptus. For example, drugs are placed in category A if adequate, well-controlled studies in pregnant humans have failed to demonstrate a risk, and in category X (contraindicated for pregnancy) if studies in animals or humans, or investigational or post-marketing reports have shown fetal risk, which clearly outweighs any possible benefit to the patient. The default category is C (risks cannot be ruled out), assigned when there is a lack of human studies and animal studies are either lacking or are positive for fetal risk, but the benefits may justify the potential risk. Categories B and D represent areas of relatively lesser, or greater concern for risk, respectively. Manson (1994) reviewed the 1992 Physicians' Desk Reference and found 7% of the 1033 drugs belonged to category X, 66% to category C, and only 0.7% to category A. The FDA categorization procedure has been criticized (Teratology Society, 1994) as being too reliant on risk/benefit comparisons, especially given that the magnitude of risk is often unknown, or the benefits are not an issue (eg, after the drug in question has been taken during early pregnancy, the question is then directed to the management of the exposed pregnancy). The FDA system has also been criticized for demanding an unrealistically high quality of data for assignment to category A (negative controlled studies in pregnant women) and overuse of category C, interpreted as "risks cannot be ruled out" (Sannerstedt *et al.*, 1996). This is an important issue because presently the perception of teratogenic risk is strong among both patients and prescribers even for safe drugs (Pole *et al.*, 2000). The often necessary reliance on studies conducted in animals has also been criticized, and acceptance by clinicians of these studies as reflective of human risks/benefits may be limited (Doering *et al.*, 2002). The approach of FDA for informing physicians and patients about the risk of drugs for use in pregnancy is currently undergoing a complete overhaul. The proposed new system eliminates the letter categories and includes a risk summary and information about available data for the drug during pregnancy.

For environmental chemicals, the purpose of the risk assessment process for noncancer endpoints such as developmental toxicity is generally to define the dose, route, timing, and duration of exposure that induces effects at the lowest level in the most relevant laboratory animal model (USEPA, 1991a,b). The exposure associated with this "critical effect" is then subjected to a variety of safety or uncertainty factors in order to derive an exposure level for humans that is presumed to be relatively safe (see Chap. 4). The principal uncertainty factors include one for interspecies extrapolation and one for variability in the human population. The default value for each of these factors is 10. In the absence of firm evidence upon which to base decisions on whether or not to extrapolate animal test data, certain default assumptions are generally made. They include (1) a chemical that produces an adverse developmental effect in experimental animals will potentially pose a hazard to humans following sufficient exposure during development; (2) all four manifestations of developmental toxicity (death, structural abnormalities, growth alterations, and functional deficits) are of concern; (3) the specific types of developmental effects seen in animal studies are not necessarily the same as those that may be produced in humans; (4) the most appropriate species is used to estimate human risk when data are available (in the absence of such data, the most sensitive species

is appropriate); and (5) in general, a threshold is assumed for the dose–response curve for agents that produce developmental toxicity.

New Approaches

The Benchmark-Dose Approach The use of safety or uncertainty factors applied to an experimentally derived NOAEL to arrive at a presumed safe level of human exposure is predicated on the risk assessment assumption that a threshold for developmental toxicity exists (see "Principles of Developmental Toxicology"). A threshold should not be confused with the NOAEL, as the NOAEL is dependent entirely on the power of the study and is associated with risks perhaps on the order of 5% over the control incidence in typical studies. Also, the value obtained by the application of uncertainty factors to the NOAEL should not be confused with a threshold, as this exposure is only assumed to be without appreciable added risk.

The use of the NOAEL in the risk assessment process has been criticized for several reasons. Because it is dependent on statistical power to detect pairwise differences between a treated and a control group, the use of larger sample sizes and more dose groups (which might better characterize the dose–response relationship) can only yield lower NOAELs, and thus better experimental designs are actually penalized by this approach. In addition, the NOAEL is limited to an experimental dose level, and an experiment might need to be repeated to develop a NOAEL for risk assessment. A final point relates to the fact that, given varying experimental designs and variability of control values, NOAELs actually represent different levels of risk in different studies.

Crump (1984) proposed using a mathematical model to estimate the lower confidence bounds on a predetermined level of risk [the "benchmark dose" (BMD)] as a means of avoiding many of the disadvantages of the NOAEL. The application of this approach to a large compilation of Segment II type data sets (Faustman *et al.*, 1994; Allen *et al.*, 1994a,b; Kavlock *et al.*, 1995) demonstrated that a variety of mathematical models, including those that incorporate developmental-specific features such as litter size and intralitter correlations, can be readily applied to standard test results. On average, benchmark doses based on a 5% added risk of effect calculated on quantal endpoints (eg, whether an implant was affected or not) were approximately equivalent to traditionally determined NOAELs. When the litter was used as the unit of response (did it contain at least one affected implant?), benchmarks calculated for a 10% added risk were most similar to the correspondingly determined NOAEL. Discrepancies between the benchmark dose and the NOAEL were most pronounced when one or more of the following conditions were present: a shallow dose–response, small sample sizes, wide spacing of experimental dosage levels, or more than the typical number of dose levels. These features tend to make determination of the NOAEL more problematic (usually higher) and the confidence limits around the maximum likelihood estimate broader (resulting in lower BMDs). Software programs, including the USEPA's Benchmark Dose Software (BMDS), are available, helping to make the BMD approach the method of choice for many risk assessment organizations worldwide (Davis *et al.*, 2011).

Biologically Based Dose–Response Modeling The introduction of statistical dose–response models for noncancer endpoints is the first step in developing quantitative, mechanistic models that will help reduce the major uncertainties of high-to-low dose and species-to-species extrapolation of experimental data. These biologically based dose–response models integrate pharmacokinetic information on target tissue dosimetry with molecular/biochemical responses, cellular/tissue responses, and developmental toxicity (O'Flaherty, 1997; Lau and Setzer, 2000; Lau *et al.*, 2001; Setzer *et al.*, 2001).

Figure 10-11. Biologically based dose response modeling of the developmental toxicity of 5-fluorouracil (5-FU) following maternal administration on gestation day 14. *Top:* Proposed model for the developmental toxicity of 5-FU based on thymidylate synthetase (TS) inhibition, decreased DNA synthesis, cell cycle alterations, and growth deficits and hind-limb dysmorphogenesis. Shaded events were measured experimentally. *Middle:* Relationships between successive endpoints are shown in these four panels (hind-limb bud TS activity versus 5-FU dose, S-phase accumulation versus TS activity, limb digit 5 area at 24 hours postdose versus proportion of cells in S phase, and digit agenesis at term versus limb digit 5 area at 24 hours). Data were fitted with Hill equations. The curves were generated by Monte-Carlo simulation to estimate variability around the predicted relationships. *Bottom:* Model for induction of hind-limb defects induced by 5-FU, generated by integration of the individual Hill equations describing the relationships between successive model endpoints as presented in the middle panels. These individual equations are listed here, and the curves were generated by Monte-Carlo simulation to estimate variability around the predicted relationship. The simulation results indicate that variability in the intermediate endpoints can account for differences between the predicted and actual dose response. AGEN: digit agenesis at term; D5A: digit 5 area; S: percent of cells in S-phase. (Adapted from Shuey *et al.* (1994), images courtesy of Dr. Woody Setzer.)

Gaylor and Razzaghi (1992) proposed a model that related induction of cleft palate to fetal growth inhibition, and Gaylor and Chen (1993) proposed a model relating fetal weight and the probability of fetal abnormality. Shuey *et al.* (1994) presented a model using the cancer chemotherapeutic 5-fluorouracil (Fig. 10-11). They

postulated that the developmental toxicity observed in the term fetus was due to an active metabolite (FdUMP) inhibiting the enzyme TS, with subsequent depletion of thymidine, decreased DNA synthetic rates, reduced cell proliferation, and ultimately, reduced tissue growth and differentiation. Each step in the process was determined

experimentally and the relationships were described by Hill equations. The individual equations were then linked in an integrated model to describe the entire relationship between administered dose and the incidence of hind-limb defects. Although this is still an empirically based model, the process clearly demonstrated the utility of the approach in understanding the relative importance of various pathways of abnormal development and in providing a basis for models that incorporate species-specific response parameters. Ultimately, biologically based dose-response (BBDR) models will need to be generalizable across dose, route of exposure, species, and perhaps even chemicals of similar mechanistic classes. Understanding the mode of action for any toxicant, including developmental toxicants, can greatly inform the human risk assessment process. Although the construction of BBDR models exemplifies the extent of sophistication and quantification to which such exercises can be pursued, even more qualitative information on modes of

action can have a great impact on the interpretation of developmental toxicity test results. For excellent examples of the utility of mode of action information, the reader is referred to an issue of *Critical Reviews in Toxicology* (September–October, 2005;35) devoted to this topic. Developmental toxicants for which mode of action is discussed include ethylene glycol (Corley *et al.*, 2005), nicotine (Slikker *et al.*, 2005), phthalate esters (Foster, 2005), vinclozolin (Kavlock and Cummings, 2005), valproic acid (Wiltse, 2005), hemoglobin-based oxygen carriers (Holson *et al.*, 2005), ACE inhibitors (Tabacova, 2005), and PTU (Zoeller and Crofton, 2005).

PATHWAYS TO THE FUTURE

In 2000, a committee assembled by the NRC released its report, “*Scientific Frontiers in Developmental Toxicology and Risk Assessment*” (NRC, 2000), which concluded that major

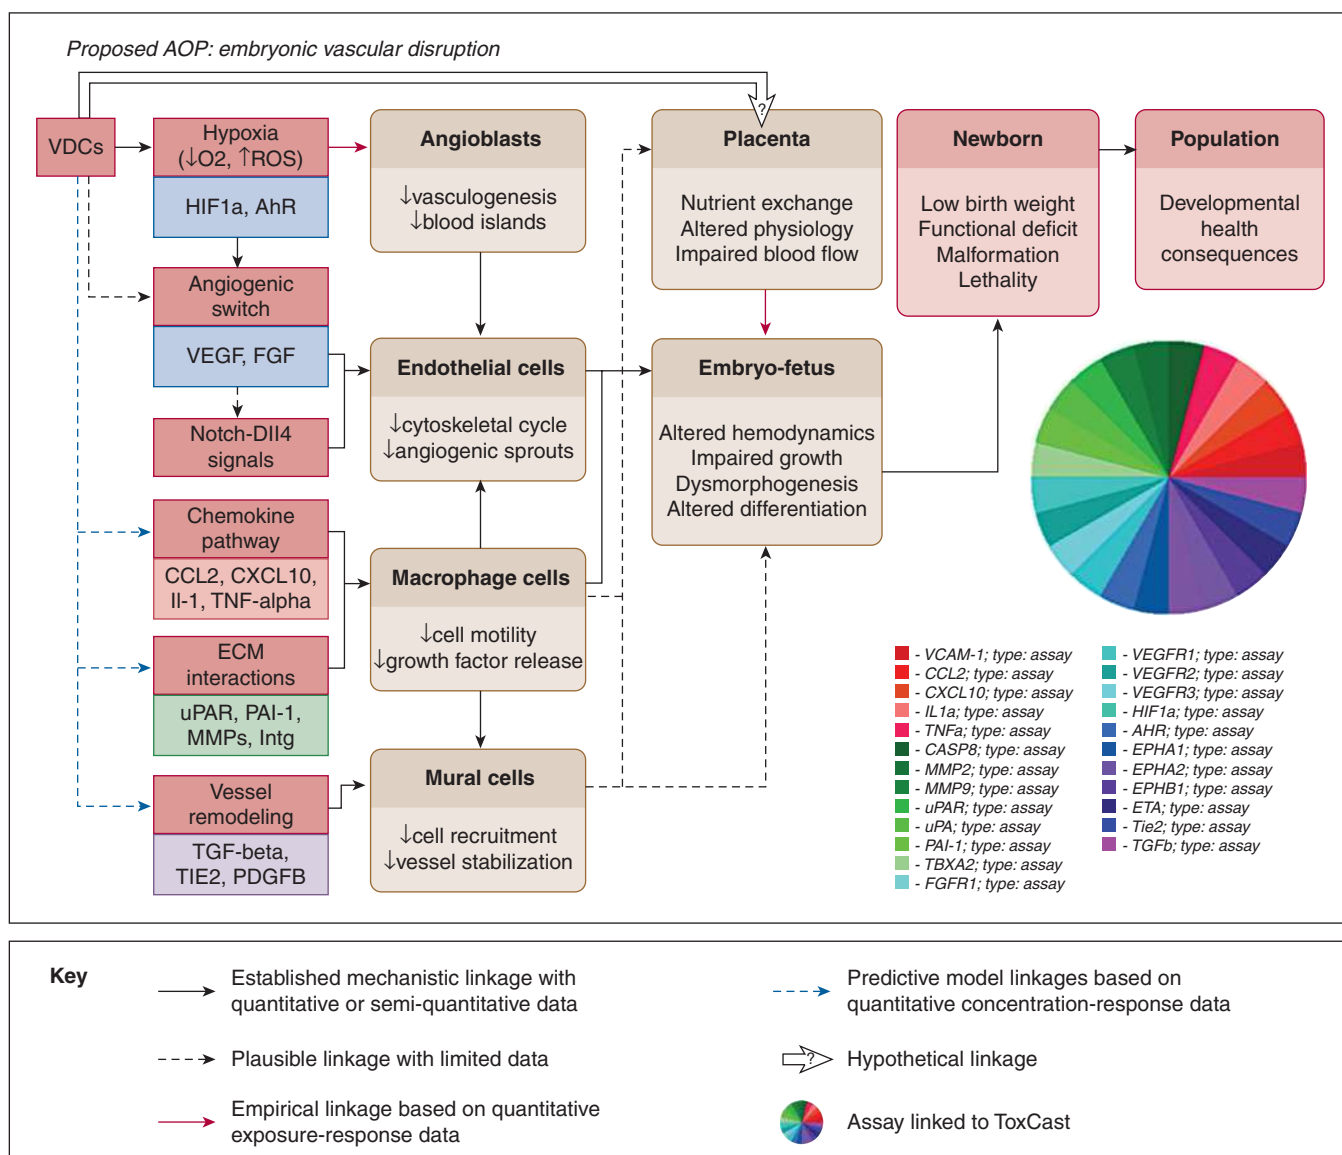

Figure 10-12. Disruption of embryonic vascular development in predictive toxicology. This model of an adverse outcome pathway (AOP) for embryonic vascular disruption was built using high-throughput screening data from the US Environmental Protection Agency’s ToxCast database (<http://actor.epa.gov/actor/faces/ToxCastDB/Home.jsp>). Anchor 1 (red boxes on the left side) addresses macromolecular interactions of the toxicant with elements of the pathway. Anchor 2 (red boxes on the right) refer to relevant organismal and population responses. The middle columns address intervening cellular and organ responses. The color wheel indicates sectors for 25 ToxCast assays shown that had evidence of abnormal embryonic vascular development based on genetic mouse models and mapped to previously identified critical pathways (toxicity data were not applied to these pathways). VDC, vascular disrupting chemical. (From Knudsen and Kleinstreuer, 2011, with permission.)

discoveries have been made about mechanisms of normal development that have been conserved in diverse animals. Many of these animals have been used extensively in developmental biology and genetics, including the fruit fly, roundworm, zebrafish, frog, chick, and mouse. That these key pathways have been preserved over millions of years of evolution and speciation provides a strong scientific rationale for using these animal models for developmental toxicology. These organisms are advantageous for developmental toxicity studies due to their well-known genetics and embryology, their rapid generation time, and the ability to manipulate their genetics to probe specific developmental pathways or to incorporate human genes, such as those of drug metabolizing enzymes, to answer questions of interspecies extrapolation. As discussed above, there has been a great deal of progress over the past decade in using alternative approaches for evaluating developmental toxicity. A more recent NRC report entitled “Toxicity Testing in the 21st Century: A Vision and Strategy” (NRC, 2007) lays out an approach toward revolutionizing the way the toxicity is assessed, moving from expensive and time-consuming animal studies to high-throughput in vitro assays based on cellular toxicity pathways and analyzing outputs using a systems biology approach. This is the basis for EPA’s ToxCast program discussed above, including assays relevant to developmental toxicity. Although full implementation of such approaches is probably years away, in the interim these assays should at least provide data for prioritizing chemicals for further study.

As our knowledge of the genetic control of normal development has advanced immensely in the past few years, so has the technology to examine gene expression and its control, networks of interrelated gene products, and changes in gene expression induced by alterations in the developmental environment. Advances in genomics, proteomics, metabolomics, and bioinformatics are being used to advance our understanding of health and disease, including normal and abnormal development. The ability to gather and analyze large amounts of biological data using databases and models of biological systems allows a more comprehensive approach to understanding pathways to developmental toxicity. Systems modeling and virtual tissues are among the nascent cutting-edge approaches being developed (Knudsen and Daston, 2010). An excellent example is the modeling of a proposed adverse outcome pathway for embryonic vascular disruption (Kleinstreuer *et al.*, 2011; Knudsen and Kleinstreuer, 2011). The model includes a number of potentially responsive gene networks involved in responses to hypoxia, the angiogenic switch, extracellular matrix interactions and vessel remodeling, as well as predicted downstream consequences of disrupting these networks (Fig. 10-12).

Public sharing of data is a trend that is increasing in biology and toxicology. The ToxRefDB database at EPA mentioned above is a searchable public database of chemical toxicity results of regulatory guideline studies, and it includes data for developmental and reproductive toxicity. Knudsen *et al.* (2009) have extracted and analyzed rodent and rabbit maternal and developmental toxicity endpoints from ToxRefDB, providing a useful data set for comparison to tests in alternative species and other purposes. Another database, simply termed “Developmental Toxicity Database,” (<http://www.ilsa.org/ResearchFoundation/Pages/DevelopmentalToxicityDatabase.aspx>) has recently been launched by the International Life Science Institute (ILSI) and includes maternal and developmental toxicity data from studies in rats, mice, rabbits, and hamsters. Databases such as these, along with advances in biology discussed above, will facilitate progress toward improving our ability to predict developmental toxicity reliably, quickly, and more economically.

BLOOD AS A TARGET ORGAN

Hematotoxicology is the study of adverse effects of drugs, nontherapeutic chemicals, and other chemicals in our environment on blood and blood-forming tissues. This subspecialty draws on the discipline of hematology and the principles of toxicology. Scientific understanding of the former began with the contributions of Leeuwenhoek and others in the 17th century with the microscopic examination of blood. Hematology was later recognized as an applied laboratory science but limited to quantitation of formed elements of the blood and the study of their morphology, along with that of bone marrow, spleen, and lymphoid tissues. It is now a diverse medical specialty, which—perhaps more than any other discipline—has made tremendous contributions to molecular medicine.

The vital functions that blood cells perform, together with the susceptibility of this highly proliferative tissue to intoxication, make the hematopoietic system unique as a target organ. Accordingly, it ranks with liver and kidney as among the most important considerations in the risk assessment of individual patient populations exposed to potential toxicants in the environment, workplace, and medicine cabinet.

The delivery of oxygen to tissues throughout the body, maintenance of vascular integrity, and provision of the many effector and immune functions necessary for host defense require a prodigious proliferative and regenerative capacity. Each of the various

blood cells (erythrocytes, granulocytes, and platelets) is produced at a rate of approximately one to three million/s in a healthy adult and several times that rate in conditions where demand for these cells is high, as in hemolytic anemia or suppurative inflammation (Kaushansky, 2006). As with intestinal mucosa and gonads, this characteristic makes hematopoietic tissue a particularly sensitive target for cytoreductive or antimetabolic agents, such as those used to treat cancer, infection, and immune-mediated disorders. This tissue is also susceptible to secondary effects of toxic agents that affect the supply of nutrients, such as iron; the clearance of toxins and metabolites, such as urea; or the production of vital growth factors, such as erythropoietin and granulocyte colony-stimulating factor (G-CSF).

The consequences of direct or indirect damage to blood cells and their precursors are predictable and potentially life-threatening. They include hypoxia, hemorrhage, and infection. These effects may be subclinical and slowly progressive or acute and fulminant, with dramatic clinical presentations. Hematotoxicity is usually assessed in the context of risk versus benefit. It may be used to define dosage in treatment modalities in which these effects are limiting, such as those employing certain anticancer, antiviral, and antithrombotic agents.

Hematotoxicity is generally regarded as unacceptable, however, in treatments for less serious illnesses, such as mild hypertension or arthritis, or following exposure to contaminated foods

or environmental contaminants. Risk-versus-benefit decisions involving hematotoxicity may be controversial, especially when the incidence of these effects is very low. Irrespective of whether the effect is linked to the pharmacologic action of the drug, as with cytoreductive or thrombolytic agents, or unrelated to its intended action, the right balance between risk and benefit is not always clear.

Hematotoxicity may be regarded as *primary*, where one or more blood components are directly affected, or *secondary*, where the toxic effect is a consequence of other tissue injury or systemic disturbances. Primary toxicity is regarded as among the more common serious effects of xenobiotics, particularly drugs (Vandendries and Drews, 2006). Secondary toxicity is exceedingly common, due to the propensity of blood cells to reflect a wide range of local and systemic effects of toxicants on other tissues. These secondary effects on hematopoietic tissue are often more reactive or compensatory than toxic and provide the toxicologist and clinician with an important and accessible tool for monitoring and characterizing toxic responses.

HEMATOPOIESIS

The production of blood cells, or hematopoiesis, is a highly regulated sequence of events by which blood cell precursors proliferate and differentiate to meet the relentless needs of oxygen transport, host defense and repair, hemostasis, and other vital functions described previously. The bone marrow is the principal site of hematopoiesis in humans and most laboratory and domestic animals. The spleen has little function in blood cell production in the healthy human but plays a critical role in the clearance of defective or senescent cells, as well as in host defense. In the human fetus, hematopoiesis can be found in the liver, spleen, bone marrow, thymus, and lymph nodes. The bone marrow is the dominant hematopoietic organ in the latter half of gestation and the only blood-cell-producing organ at birth (Moore, 1975). All marrow is active, or “red marrow,” at birth (Hudson, 2006). During early childhood, hematopoiesis recedes in long bones and, in adults, is confined to the axial skeleton and proximal humerus and femur (Custer and Ahlfeldt, 1932). The marrow in the distal long bones becomes “yellow” or fatty. When demand for blood cell production is great, as with certain disease states, fatty marrow can be reactivated as sites of hematopoiesis (Fig. 11-1). This can be useful in toxicology studies as a marker of sustained hematopoietic stress, as exemplified in studies on the hematopathology of cephalosporin toxicity in the dog (Bloom *et al.*, 1987). Under extreme conditions, embryonic patterns of hematopoiesis may reappear as *extramedullary hematopoiesis* (Young and Weiss, 1997).

While the central function of bone marrow is hematopoiesis and lymphopoiesis, bone marrow is also one of the sites of the mononuclear phagocyte system (MPS), contributing monocytes that differentiate into a variety of MPS cells located in liver (Kupffer cells), spleen (littoral cells), lymph nodes, and other tissues. Conventional histologic and cytologic sampling of bone marrow reveals a very limited picture of an exceedingly complex tissue containing erythroid, granulocytic, megakaryocytic, MPS, and lymphoid precursors in varied stages of maturation; stromal cells; and vasculature all encased by bone (Fig. 11-1). Routine examinations of such specimens in our pathology and toxicology laboratories cannot possibly reveal the sophisticated interactions that mediate lineage commitment, proliferation, differentiation, acquisition of functional characteristics, and trafficking that result in the delivery of mature cells to the circulation, as required in sickness

and in health. Exactly how the process of hematopoietic progenitor cell differentiation and maturation and subsequent release into the peripheral circulation is so tightly regulated is not fully known. Early and elegant morphologic studies revealed a complex interplay of developing cells with stromal cells, extracellular matrix components, and cytokines that make up the *hematopoietic inductive microenvironment* (HIM) (Young and Weiss, 1997). More recent studies have shown that each lineage, and even stage of maturation, is supported within a specific niche that is maintained by the surrounding stromal cells (Heissig *et al.*, 2005). An array of cytokines and chemokines directs a particular progenitor cell to the appropriate niche (Lataillade *et al.*, 2004). Today’s powerful research tools, which include the use of knockout mice, have begun to define how hematopoietic growth factors, cytokines, and chemokines interact with the HIM and other tissues to control the production and trafficking of blood cells (Kaushansky, 2006; Laurence, 2006). These tools also include the evolving applications of systems biology, which uses a combination of mathematical, engineering, and computational tools for constructing and validating models for studying complex biologic phenomena such as hematopoieses (Whichard *et al.*, 2010). These understandings are providing opportunities to develop promising therapies that are now presenting new pharmacologic and toxicologic challenges.

TOXICOLOGY OF THE ERYTHRON

The Erythrocyte

Erythrocytes (red blood cells [RBCs]) make up 40% to 45% of the circulating blood volume and serve as the principal vehicle of transportation of oxygen from the lungs to the peripheral tissues. In addition, erythrocytes are involved in the transport of carbon dioxide from tissues to the lung, maintenance of a constant pH in blood, and regulation of blood flow to tissues (Hsia, 1998; Kim-Shapiro *et al.*, 2005). Erythrocytes help modulate the inflammatory response through clearance of immune complexes containing complement components and through interaction with nitric oxide, a potent vasodilator (Kim-Shapiro *et al.*, 2005; Lindorfer *et al.*, 2001). An area of developing interest is the role of erythrocytes as a carrier and/or reservoir for drugs and toxins (Schrijvers *et al.*, 1999). The effect of xenobiotics on erythrocytes has been extensively evaluated, because of both the ready access to the tissue and the frequency with which xenobiotics cause changes in this critical tissue.

Xenobiotics may affect the production, function, and/or survival of erythrocytes. These effects are most frequently manifest as a change in the circulating red cell mass, usually resulting in a decrease (anemia). Occasionally, agents that increase oxygen affinity lead to an increase in red cell mass (erythrocytosis), but this is distinctly less common. Shifts in plasma volume can alter the relative concentration of erythrocytes/hemoglobin and can be easily confused with true anemia or erythrocytosis.

There are two general mechanisms that lead to true anemia—either decreased production or increased erythrocyte destruction. Both mechanisms may be operative in some disorders, or a combination may arise due to the imposition of a second disorder on a compensated underlying problem. For example, patients with compensated congenital hemolytic anemias are very susceptible to additional insults that may precipitate an acute drop in a previously stable red cell mass, such as parvovirus infection-associated suppression of erythropoiesis.

Evaluation of a peripheral blood sample can provide evidence for the underlying mechanism of anemia. The usual parameters

Figure 11-1. Bone marrow schema. Several venous sinuses (Sinus), cut longitudinally, drain into the central longitudinal vein, cut in cross-section. A branch of the nutrient artery (Artery) and an arterial capillary (Arter Capil) are present. The circulation in the bone marrow, as in the other tissues of the body save the spleen, is “closed,” that is, there is endothelial continuity from artery into vein. Veins in bone marrow have in common with veins elsewhere the primary function of returning blood to the heart. Marrow veins, in addition, possess the distinctive function of receiving blood cells produced and stored in the marrow and carrying them to thymus or spleen, or into the general circulation, for further maturation, widespread distribution, and function. The hematopoietic compartments of the bone marrow consist of hematopoietic cells in varying stages of differentiation supported by a fibroblastic stroma. They lie between the most proximal veins, termed venous sinuses or vascular sinuses. When hematopoiesis is rather quiet and few nascent blood cells cross the wall of vascular sinuses, moving from hematopoietic compartments into the sinus lumen, the wall of the sinus tends to be trilaminar, consisting of endothelium (end), wispy basement membrane (in stipple), and adventitial reticular cells (adv) that form an incomplete outermost layer and branch out into the hematopoietic compartment, forming a scaffolding enclosing and supporting the hematopoietic cells. Thus, adventitial reticular cells are both vascular, as the outermost wall of the vascular sinus, and stromal, branching into the perivascular hematopoietic space, holding the vascular sinus in place and supporting hematopoietic cells. Where hematopoietic cell traffic across the wall of the venous sinus is heightened, the adventitial cell cover is retracted and a larger expanse of endothelium, covered only by wisps of basement membrane, is exposed to the hematopoietic cells, facilitating their transmural cell passage. Where transmural cell passage is greatly reduced, adventitial cells accumulate fat and become rounded and bulky, now termed adipocytes, impeding hematopoietic cell passage, and occupying space in the hematopoietic compartment that, when they transform again to adventitial cells flattened upon veins, yield to hematopoiesis. These fibroblastic stromal cells in the marrow of central bones can modulate readily to and from adventitial cell and adipocyte and retain their granulocyte inductive capacities in either form. In the distal limb and tail bones, where there is little hematopoiesis, they assume the adipocyte form in such large numbers that the marrow is grossly yellow. These adipocytes lose fat only in marked hematopoietic stress, as in spherocytic and other severe anemias where this marrow becomes hematopoietic and grossly red. In such stress, moreover, barrier cells may augment or replace adventitial reticular cells and even endothelial cells. Thus, adventitial cells/adipocytes, by their disposition and bulk, mechanically regulate hematopoiesis and blood cell delivery. In addition, they do so in a subtle manner, through paracrine secretion of several small-protein regulatory factors termed cytokines, which include interleukins. (Reprinted from Young and Weiss [1997], with permission from the authors and Elsevier Science.)

of a complete blood count (CBC)—including the RBC count, hemoglobin concentration (Hgb), and hematocrit (also referred to as packed cell volume [PCV])—can establish the presence of anemia. Two additional parameters helpful in classifying an anemia are the mean corpuscular volume (MCV) and the reticulocyte count. Increased destruction is usually accompanied by an increase in reticulocytes (young erythrocytes containing residual RNA), which are easily enumerated using appropriate stains. The introduction of automated methods has improved the precision of reticulocyte counting and introduced new parameters that aid in

characterization of red cell production. With these new methods, reticulocyte counting may also be useful in conditions associated with decreased production, particularly when assessing response to therapy. Other readily performed parameters helpful in the evaluation of the human erythron include erythrocyte morphology (eg, megaloblastic changes, erythrocyte fragmentation, sickled RBCs); serum concentration of haptoglobin, lactic dehydrogenase (LD), free hemoglobin, vitamin B₁₂, folate, iron, and ferritin; direct and indirect red cell antiglobulin tests; and bone marrow morphology (Prchal, 2006; Ryan, 2006).

Alterations in Red Cell Production

Erythrocyte production is a continuous process that is dependent on frequent cell division and a high rate of hemoglobin synthesis. Human adult hemoglobin (hemoglobin A), the major constituent of the erythrocyte cytoplasm, is a tetramer composed of two α -globin and two β -globin chains, each with a heme residue located in a stereospecific pocket of the globin chain. Synthesis of hemoglobin is dependent on coordinated production of globin chains and heme moieties. Abnormalities that lead to decreased hemoglobin synthesis are relatively common (eg, iron deficiency) and are often associated with a decrease in the MCV and hypochromasia (increased central pallor of RBCs on stained blood films due to the low hemoglobin concentration).

An imbalance between α - and β -chain production is the basis of congenital thalassemia syndromes and results in decreased hemoglobin production and microcytosis (Weatherall, 2006). Xenobiotics can affect globin chain synthesis and alter the composition of hemoglobin within erythrocytes. This is perhaps best demonstrated by hydroxyurea, which has been found to increase the synthesis of γ -globin chains. The γ -globin chains are a normal constituent of hemoglobin during fetal development, replacing the β chains in the hemoglobin tetramer (hemoglobin F, $\alpha_2\gamma_2$). Hemoglobin F has a higher affinity for oxygen than hemoglobin A and can protect against crystallization (sickling) of deoxyhemoglobin S in sickle cell disease (Steinberg, 2006).

Synthesis of heme requires incorporation of iron into a porphyrin ring (Fig. 11-2) (Napier *et al.*, 2005; Ponka, 1997). Iron

Table 11-1

Xenobiotics Associated with Sideroblastic Anemia

Cycloserine	Lead intoxication

deficiency is usually the result of dietary deficiency or increased blood loss. Drugs that contribute to blood loss, such as nonsteroidal anti-inflammatory agents, with their increased risk of gastrointestinal ulceration and bleeding, may potentiate the risk of developing *iron deficiency anemia*. Defects in the synthesis of porphyrin ring of heme can lead to *sideroblastic anemia*, with its characteristic accumulation of iron in bone marrow erythroblasts. The accumulated iron precipitates within mitochondria in a complex with mitochondrial ferritin, causing the characteristic staining pattern of ringed sideroblasts evident on iron stains such as Prussian blue (Cazzola *et al.*, 2003). A number of xenobiotics (Table 11-1) can interfere with one or more of the steps in erythroblast heme synthesis and result in sideroblastic anemia (Alcindor and Bridges, 2002; Beutler, 2006a,b,c; Fiske *et al.*, 1994).

Hematopoiesis requires active DNA synthesis and frequent mitoses. Folate and vitamin B₁₂ are necessary to maintain synthesis of thymidine for incorporation into DNA (Fig. 11-3). Deficiency of folate and/or vitamin B₁₂ results in *megaloblastic anemia*, with its

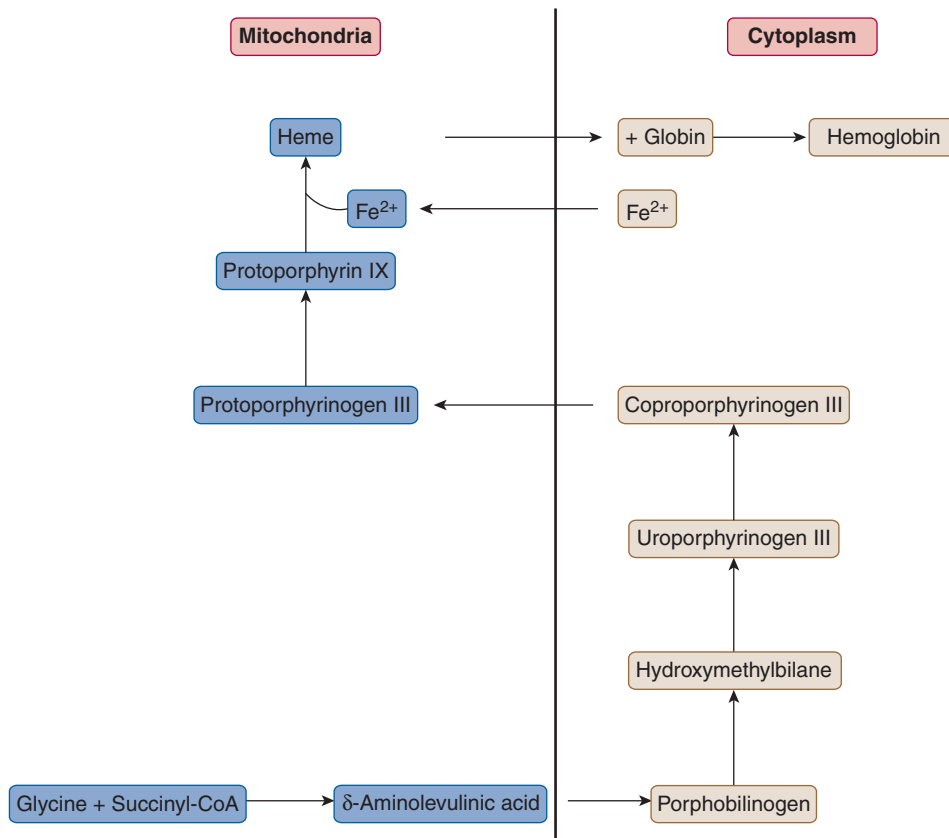

Figure 11-2. The synthesis of heme involves a series of reactions that occur in the cytoplasm and mitochondria of erythroblasts. The initial step in the pathway is the mitochondria synthesis of δ -aminolevulinic acid, a step that is commonly affected by xenobiotics, including lead. Ferrochelatase catalyzes the incorporation of ferrous iron into the tetrapyrrole protoporphyrin IX. Inhibition of the synthetic pathway leading to protoporphyrin IX, as occurs in the sideroblastic anemias, can cause an imbalance between iron concentration and ferrochelatase activity, resulting in iron deposition within mitochondria. Mitochondrial accumulation of iron is the hallmark lesion of the sideroblastic anemias.

Figure 11-3. Both tetrahydrofolate (THF) and cobalamin (CB, or vitamin B₁₂) are necessary for the synthesis of thymidine (dTMP) for incorporation into DNA. Folate enters the cell as a monoglutamate (CH₃THF) but is transformed to a polyglutamate within the cell, a step that helps prevent leakage of folate back across the cell membrane. However, CH₃THF cannot be conjugated with glutamate. CB is necessary for demethylation of the folate, allowing formation of conjugated (polyglutamate) folate (THF_n). In the absence of CB, folate levels within the cell drop, causing a functional deficiency of folate and impairing synthesis of thymidine.

characteristic morphologic and biochemical changes (Table 11-2), which commonly affect erythroid, myeloid, and megakaryocytic lineages. A number of xenobiotics may contribute to a deficiency of vitamin B₁₂ and/or folate (Table 11-3), leading to megaloblastic anemia (Babior, 2006).

Many of the antiproliferative drugs used in the treatment of malignancy predictably inhibit hematopoiesis, including erythropoiesis. The resulting bone marrow toxicity may be dose-limiting, as previously discussed. Drugs, such as amifostine, have been developed that may help protect against the marrow toxicity of these agents (Phillips, 2002). The development of recombinant forms of some of the growth factors that regulate hematopoiesis has helped shorten the duration of bone marrow suppression. As with other therapeutic proteins, there is a risk of antibody formation in response to administration of these proteins; if the antibody reacts with the endogenous growth factor, it may cause profound cytopenia (Bennett *et al.*, 2004; Li *et al.*, 2001).

Erythropoietin is commonly used to support red cell production in patients undergoing chemotherapy and with renal failure. Following a change in formulation, a series of cases of red cell aplasia associated with erythropoietin use was reported

Table 11-2

Laboratory Features of Megaloblastic Anemia

MORPHOLOGY	BIOCHEMISTRY
Peripheral blood	Peripheral blood
Pancytopenia	Decreased B ₁₂ and/or folate
Macrocytosis (↑ MCV)	Increased LD
Oval macrocytes	Antiparietal cell antibodies
Hypersegmented neutrophils	Antibody to intrinsic factor
Variation in RBC shape	Increased serum iron
Bone marrow	Hypokalemia
Erythroid hyperplasia	
Megaloblastic anemia	
Giant band neutrophils	
Giant metamyelocytes

Xenobiotics Associated with Megaloblastic Anemia

B ₁₂ DEFICIENCY	FOLATE DEFICIENCY
Paraminosalicylic acid	Phenytoin
Colchicine	Primidone
Neomycin	Carbamazepine
Ethanol	Phenobarbital
Omeprazole	Sulfasalazine
Hemodialysis	Cholestyramine
Zidovudine	Triamterine
Fish tapeworm	Malabsorption syndromes
	Antimetabolites

(Bennett *et al.*, 2004). The etiology was antibodies to the synthetic protein that cross-reacted with endogenous erythropoietin. A change in formulation in combination with the nature of the storage container and route of administration is thought to have promoted the formation of protein aggregates, a phenomenon known to be associated with an increased risk of antibody formation (Koren *et al.*, 2002). The incidence of red cell aplasia appears to have diminished following a change in packaging and administration of erythropoietin by intravenous injection (Bennett *et al.*, 2004).

Drug-induced *aplastic anemia* may represent either a predictable or idiosyncratic reaction to a xenobiotic. This life-threatening disorder is characterized by peripheral blood pancytopenia, reticulocytopenia, and bone marrow hypoplasia (Vandendries and Drews, 2006; Young, 1999, 2000). Agents such as benzene and radiation have a *predictable* effect on hematopoietic progenitors, and the resulting aplastic anemia corresponds to the magnitude of the exposure to these agents. In contrast, idiosyncratic aplastic anemia does not appear to be related to the dose of the agent initiating the process. A long list of chemicals has been associated with the development of aplastic anemia (Table 11-4), many of which have been reported in only a few patients. The principal mechanisms of aplastic anemia, as with the more common agranulocytosis, are still debated. Immune mechanisms have long been thought to contribute to the development of both idiosyncratic disorders, as discussed in greater detail in the next section. However, it has been, up until recently, difficult to obtain definitive evidence for humoral and/or cellular mechanisms of marrow suppression (Vandendries and Drews, 2006; Young, 2000). Recent observations have strongly suggested that both toxicities are immune-mediated, often involving altered proteins through reactive metabolite-mediated damage (Zhang *et al.*, 2011).

Pure red cell aplasia is a syndrome in which the decrease in marrow production is limited to the erythroid lineage (Djaldetti *et al.*, 2003; Fisch *et al.*, 2000). It is an uncommon disorder that may be due to genetic defects, infection (parvovirus B19), immune-mediated injury, myelodysplasia, drugs, or other toxins. As pure red cell aplasia occurs sporadically and infrequently, the linkage between drug exposure and pathogenesis of the aplasia remains speculative for some agents. The drugs most clearly implicated and for which there are multiple case reports include isoniazid, phenytoin, and azathioprine. The mechanism of drug-induced pure red cell aplasia is unknown, but some evidence suggests that it may also be immune-mediated. Patients with drug-induced red cell aplasia should not be reexposed to the purported offending chemical. As noted above, pure red aplasia may also occur as a consequence of an immune response to therapeutic erythropoietin.

Table 11-4

Drugs and Other Chemicals Associated with the Development of Aplastic Anemia

Chloramphenicol	Organic arsenicals	Quinacrine
Methylphenylethylhydantoin	Trimethadione	Phenylbutazone
Gold	Streptomycin	Benzene
Penicillin	Allopurinol	Tetracycline
Methicillin	Sulfonamides	Chlortetracycline
Sulfisoxazole	Sulfamethoxypyridazine	Amphotericin B
Mefloquine	Ethosuximide	Felbamate
Carbimazole	Methylmercaptoimidazole	Potassium perchlorate
Propylthiouracil	Tolbutamide	Pyrimethamine
Chlorpropamide	Carbutamide	Tripelethamine
Indomethacin	Carbamazepine	Diclofenac
Meprobamate	Chlorpromazine	Chlordiazepoxide
Mepazine	Chlorophenothane	Parathion
Thiocyanate	Methazolamide	Dinitrophenol
Bismuth	Mercury	Chlordane
Carbon tetrachloride	Cimetidine	Metolazone
Azidothymidine	Ticlopidine	Isoniazid
Trifluoperazine	D-Penicillamine	

Alterations in the Respiratory Function of Hemoglobin

Hemoglobin is necessary for effective transport of oxygen and carbon dioxide between the lungs and tissues. The respiratory function of hemoglobin has been studied in detail, revealing an intricately balanced system for the transport of oxygen from the lungs to the tissues (Hsia, 1998). Electrostatic charges hold the globin chains of deoxyhemoglobin in a “tense” (T) conformation characterized by a relatively low affinity for oxygen. Binding of oxygen alters this conformation to a “relaxed” (R) conformation that is associated with a 500-fold increase in oxygen affinity. Thus, the individual globin units show cooperativity in the binding of oxygen, resulting in the familiar sigmoid shape to the oxygen dissociation curve (Fig. 11-4). The ability of hemoglobin to safely and efficiently transport oxygen is dependent on both intrinsic (homotropic) and extrinsic (heterotropic) factors that affect the performance of this system.

Homotropic Effects One of the most important homotropic properties of oxyhemoglobin is the slow but consistent oxidation of heme iron to the ferric state to form methemoglobin (Percy *et al.*, 2005). Methemoglobin is not capable of binding and transporting oxygen. In addition, the presence of methemoglobin in a hemoglobin tetramer has allosteric effects that increase the affinity of oxyhemoglobin for oxygen, resulting in a leftward shift of the oxygen dissociation curve (Fig. 11-4). The combination of decreased oxygen content and increased affinity may significantly impair delivery of oxygen to tissues when the concentration of methemoglobin rises beyond critical levels (Hsia, 1998; Percy *et al.*, 2005).

Not surprisingly, the normal erythrocyte has metabolic mechanisms for reducing heme iron back to the ferrous state; these mechanisms are normally capable of maintaining the concentration of methemoglobin at less than 1% of total hemoglobin (Percy *et al.*, 2005). The predominant pathway is cytochrome b_5 methemoglobin reductase, which is dependent on reduced nicotinic adenine dinucleotide (NADH) and is also known as NADH diaphorase. An alternate pathway involves a reduced nicotinic adenine dinucleotide phosphate (NADPH) diaphorase that reduces a flavin that in turn reduces methemoglobin. This pathway usually accounts for less

than 5% of the reduction of methemoglobin, but its activity can be greatly enhanced by methylene blue, which is reduced to leukomethylene blue by NADPH diaphorase. Leukomethylene blue then reduces methemoglobin to deoxyhemoglobin.

A failure of these control mechanisms leads to increased levels of methemoglobin, or *methemoglobinemia*. The most common cause of methemoglobinemia is exposure to an oxidizing xenobiotic that overwhelms the NADH diaphorase system. A large number of chemicals and therapeutic agents may cause methemoglobinemia

Figure 11-4. The normal oxygen dissociation curve (solid line) has a sigmoid shape due to the cooperative interaction between the four globin chains in the hemoglobin molecule. Fully deoxygenated hemoglobin has a relatively low affinity for oxygen. Interaction of oxygen with one heme-iron moiety induces a conformational change in that globin chain. Through surface interactions, that conformational change affects the other globin chains, causing a conformational change in all of the globin chains that increases their affinity for oxygen. Homotropic and heterotropic parameters also affect the affinity of hemoglobin for oxygen. An increase in oxygen affinity results in a shift to the left in the oxygen dissociation curve. Such a shift may decrease oxygen delivery to the tissues. A decrease in oxygen affinity results in a shift to the right in the oxygen dissociation curve, facilitating oxygen delivery to the tissues.

Table 11-5

Xenobiotics Associated with Methemoglobinemia

THERAPEUTIC AGENTS	ENVIRONMENTAL AGENTS
Benzocaine	Nitrites
Lidocaine	Nitrates
Prilocaine	Nitrobenzenes
Dapsone	Aniline dyes and aniline derivatives
Amyl nitrate	Butyl nitrite
Isobutyl nitrite	Potassium chlorate
Nitroglycerine	Gasoline additives
Primaquine	Aminobenzenes
Sulfonamide	Nitrotoluenes
Phenacetin	Trinitrotoluene
Nitric oxide	Nitroethane
Phenazopyridine	<i>ortho</i> -Toluidine
Metoclopramide	<i>para</i> -Toluidine
Flutamide	β -Naphthol disulfonate
Silver nitrate	
Quinones	
Methylene blue	

(Table 11-5) (Bradberry *et al.*, 2001; Bradberry, 2003; Coleman and Coleman, 1996). These chemicals may be divided into direct oxidizers, which are capable of inducing methemoglobin formation when added to erythrocytes *in vitro* or *in vivo*, and indirect oxidizers, which do not induce methemoglobin formation when exposed to erythrocytes *in vitro* but do so after metabolic modification *in vivo*. Nitrites appear to be able to interact directly with heme to facilitate oxidation of heme iron, but the precise mechanism that leads to methemoglobin formation is unknown for many of the other substances listed in Table 11-5.

The development of methemoglobinemia may be slow and insidious or abrupt in onset, as with the use of some topical anesthetics (Bradberry *et al.*, 2001; Bradberry, 2003; Khan and Kruse, 1999; Nguyen *et al.*, 2000). Most patients tolerate low levels (<10%) of methemoglobin without clinical symptoms. Cyanosis is often evident when the methemoglobin concentration exceeds 5% to 10%. Levels above 20% are generally clinically significant and some patients may begin to manifest symptoms related to tissue hypoxemia at methemoglobin levels between 10% and 20%. The severity of clinical manifestations increases as the concentration rises above 20% to 30%, with methemoglobin levels above 70% being life-threatening. Intravenous administration of one to two mg/kg methylene blue is effective in rapidly reversing methemoglobinemia through activation of the NADPH diaphorase pathway (Clifton and Leikin, 2003). The effect of methylene blue is dependent on an adequate supply of NADPH. Consequently, methylene blue is not effective in patients with glucose-6-phosphate dehydrogenase (G-6-PD) deficiency because of the decreased capacity to form NADPH (Bradberry, 2003; Coleman and Coleman, 1996).

Heterotropic Effects There are three major heterotropic effectors of hemoglobin function: pH, erythrocyte 2,3-bisphosphoglycerate (2,3-BPG, formerly designated 2,3-diphosphoglycerate) concentration, and temperature (Hsia, 1998). A decrease in pH (eg, lactic acid, carbon dioxide) lowers the affinity of hemoglobin for oxygen, that is, it causes a right shift in the oxygen dissociation curve, facilitating the delivery of oxygen to tissues (Fig. 11-4). As bicarbonate and carbon dioxide equilibrate in the lung, the hydrogen ion concentration decreases, increasing the affinity of hemoglobin for oxygen and facilitating oxygen uptake. Thus, the

buffering capacity of hemoglobin also serves to improve oxygen uptake and delivery.

The binding site for 2,3-BPG is located in a pocket formed by the 2 β chains of a hemoglobin tetramer. Binding of 2,3-BPG to deoxyhemoglobin results in stabilization of the “T” conformation, with reduced oxygen affinity (a shift to the right of the oxygen dissociation curve). The conformational change induced by binding of oxygen alters the binding site for 2,3-BPG and results in release of 2,3-BPG from hemoglobin. This facilitates uptake of more oxygen for delivery to tissues. The concentration of 2,3-BPG increases whenever there is tissue hypoxemia but may decrease in the presence of acidosis or hypophosphatemia. Thus, hypophosphatemia may result in a left shift of the oxygen dissociation curve.

Clofibric acid and bezafibrate are capable of lowering the oxygen affinity of hemoglobin, analogous to 2,3-BPG (Poyart *et al.*, 1994). However, the association constant of bezafibrate for hemoglobin is too low for there to be a meaningful effect *in vivo*. Work continues on bezafibrate derivatives that may lower oxygen affinity and enhance tissue oxygenation. In contrast, some aromatic benzaldehydes have been shown to increase oxygen affinity and shift the dissociation curve to the left. It was thought that these compounds may be useful in preventing the sickling of deoxyhemoglobin S in patients with sickle cell disease. However, these and other chemicals evaluated for their effect on hemoglobin oxygen affinity have not progressed into clinical usage (Papassotiriou *et al.*, 1998; Poyart *et al.*, 1994).

The oxygen affinity of hemoglobin decreases as the body temperature increases (Hsia, 1998). This facilitates delivery of oxygen to tissues during periods of extreme exercise and febrile illnesses associated with increased temperature. Correspondingly, oxygen affinity increases during hypothermia, which may lead to decreased oxygen delivery under these conditions. This must be taken into consideration during surgical procedures during which there is induction of deep hypothermia.

The respiratory function of hemoglobin may also be impaired by blockade of the ligand binding site following interaction with other substances, most notably carbon monoxide (Hsia, 1998). Carbon monoxide has a relatively low rate of association with deoxyhemoglobin but has high affinity once bound. The affinity is about 200 times that of oxygen, and thus persistent exposure to a low level of carbon monoxide (eg, 0.1%) may lead to 50% saturation of hemoglobin. Binding of carbon monoxide also results in stabilization of the hemoglobin molecule in the high-affinity “R” conformation. Consequently, the oxygen dissociation curve is shifted to the left, further compromising oxygen delivery to the tissues. Carbon monoxide is produced at low levels by the body through the metabolism of heme and equilibrates across the pulmonary capillary/alveolar bed. Low concentrations of carboxyhemoglobin can be cytoprotective during inflammatory stress or ischemia/reperfusion injury and the therapeutic use of low concentrations of carbon monoxide is being explored (Kao and Nanagas, 2005; Ryter and Otterbein, 2004).

The major sources of significant exogenous exposure to carbon monoxide are smoking and burning of fossil fuels (including automobiles), particularly in enclosed spaces. Heavy smoking during pregnancy may result in significant levels of carboxyhemoglobin in fetal blood and diminished oxygenation of fetal tissues. Symptoms of carbon monoxide toxicity, such as dizziness, shortness of breath, and headache, begin to appear when carboxyhemoglobin levels reach 20%. Levels of 50% to 80% carboxyhemoglobin may be lethal. In addition to effects due to interaction with hemoglobin, CO may cause toxicity through effects on myoglobin, cytochromes, guanylate cyclase, or nitric oxide. The key to therapy is removal

from the source of carbon monoxide and provision of an adequate supply of oxygen; hyperbaric hyperoxia may be used in serious cases (Kao and Nanagas, 2005; Ryter and Otterbein, 2004).

Methemoglobin can combine reversibly with a variety of chemical substances, including cyanide, sulfides, peroxides, fluorides, and azides. The affinity of methemoglobin for cyanide is utilized in two settings. First, nitrites are administered in cyanide poisoning to form methemoglobin, which then binds free cyanide, sparing other critical cellular respiratory enzymes (Cummings, 2004). Second, formation of cyanmethemoglobin by reaction of hemoglobin with potassium ferricyanide is a standard method for measurement of hemoglobin concentration.

Nitric oxide, an important vasodilator that modulates vascular tone, binds avidly to heme iron. An additional function of erythrocytes is related to this interaction, which can influence the availability of nitric oxide in parts of the circulation (Hsia, 1998; Lundberg and Weitzberg, 2005). Solutions of hemoglobin have been evaluated as a potential replacement for RBC transfusions. However, these trials have been halted due to the toxicity associated with administration of hemoglobin solutions. Vascular instability is one of the complications associated with infusion of hemoglobin solutions and is thought to be related to the scavenging of essential nitric oxide by the administered hemoglobin (Moore *et al.*, 2005; Rother *et al.*, 2005).

Alterations in Erythrocyte Survival

The normal survival of erythrocytes in the circulation is about 120 days (Dessypris, 1999). During this period the erythrocytes are exposed to a variety of oxidative injuries and must negotiate the tortuous passages of the microcirculation and the spleen. This requires a deformable cell membrane and energy to maintain the sodium–potassium gradients and repair mechanisms (Van Wijk and van Solinge, 2005). Very little protein synthesis occurs during this time, as erythrocytes are anucleate when they enter the circulation and residual mRNA is rapidly lost over the first one to two days in the circulation. Consequently, senescence occurs over time until the aged erythrocytes are removed by the spleen, where the iron is recovered for reutilization in heme synthesis. Any insult that increases oxidative injury, decreases metabolism, or alters the membrane may cause a decrease in erythrocyte concentration and a corresponding anemia.

Nonimmune Hemolytic Anemia

Microangiopathic Anemias Intravascular fragmentation of erythrocytes gives rise to the *microangiopathic hemolytic anemias* (Baker, 2006). The hallmark of this process is the presence of schistocytes (fragmented RBCs) in the peripheral blood. These abnormal cellular fragments are usually promptly cleared from the circulation by the spleen. Thus, their presence in peripheral blood samples indicates either an increased rate of formation or abnormal clearance function of the spleen. The formation of fibrin strands in the microcirculation is a common mechanism for RBC fragmentation. This may occur in the setting of disseminated intravascular coagulation, sepsis, the hemolytic-uremic syndrome (HUS), and thrombotic thrombocytopenic purpura (TTP). The erythrocytes are essentially sliced into fragments by the fibrin strands that extend across the vascular lumen and impede the flow of erythrocytes through the vasculature. Excessive fragmentation can also be seen in the presence of abnormal vasculature, as occurs with damaged cardiac valves, arteriovenous malformations, vasculitis, and widely metastatic carcinoma (Baker, 2006). The high shear associated with malignant hypertension may also lead to RBC fragmentation.

Other Mechanical Injuries March hemoglobinuria is an episodic disorder characterized by destruction of RBCs during vigorous exercise or marching (Abarbanel *et al.*, 1990; Sagov, 1970). The erythrocytes appear to be destroyed by mechanical trauma in the feet. Sufficient hemoglobin may be released to cause hemoglobinuria. The disorder should be distinguished from other causes of intermittent hemoglobinuria such as paroxysmal nocturnal hemoglobinuria. The introduction of improved footwear for athletes and soldiers has significantly decreased the incidence of this problem.

Major thermal burns are also associated with a hemolytic process. The erythrocyte membrane becomes unstable as the temperature increases. With major burns there can be significant heat-dependent lysis of erythrocytes. Small RBC fragments break off, with resealing of the cell membrane. These cell fragments usually assume a spherical shape and are not as deformable as normal erythrocytes. Consequently, these abnormal cell fragments are removed in the spleen, leading to an anemia. The burden of RBC fragments may impair the phagocytic function of the spleen, contributing to the increased susceptibility to endotoxic shock following major burns (Hatherill *et al.*, 1986; Schneidkraut and Loegering, 1984).

Infectious Diseases A variety of infectious diseases may be associated with significant hemolysis, by either direct effect on the erythrocyte or development of an immune-mediated hemolytic process (Berkowitz, 1991; Beutler, 2006a,b,c). The most common agents that directly cause hemolysis include malaria, babesiosis, clostridial infections, and bartonellosis. Erythrocytes are parasitized in malaria and babesiosis, leading to their destruction. Clostridial infections are associated with release of hemolytic toxins that enter the circulation and lyse erythrocytes. The hemolysis can be severe with significant hemoglobinuria, even with apparently localized infections. *Bartonella bacilliformis* is thought to adhere to the erythrocyte, leading to rapid removal from the circulation. The hemolysis can be severe and the mortality rate in this disorder (Oroya fever) is high.

Oxidative Hemolysis Molecular oxygen is a reactive and potentially toxic chemical species; consequently, the normal respiratory function of erythrocytes generates oxidative stress on a continuous basis. The major mechanisms that protect against oxidative injury in erythrocytes include NADH diaphorase, superoxide dismutase, catalase, and the glutathione pathway (Coleman and Coleman, 1996; Njalsson and Norgren, 2005). As indicated previously, a small amount of methemoglobin is continuously formed during the process of loading and unloading of oxygen from hemoglobin. Formation of methemoglobin is associated with formation of superoxide free radicals, which must be detoxified to prevent oxidative injury to hemoglobin and other critical erythrocyte components. Under physiologic conditions, superoxide dismutase converts superoxide into hydrogen peroxide, which is then metabolized by catalase and glutathione peroxidase (Fig. 11-5).

A number of xenobiotics, particularly compounds containing aromatic amines, are capable of inducing oxidative injury in erythrocytes (Table 11-6) (Bradberry, 2003; Percy *et al.*, 2005). These chemicals appear to potentiate the normal redox reactions and are capable of overwhelming the usual protective mechanisms. The interaction between these xenobiotics and hemoglobin leads to the formation of free radicals that denature critical proteins, including hemoglobin, thiol-dependent enzymes, and components of the erythrocyte membrane. In the presence of hydrogen peroxide and xenobiotics such as hydroxylamine, hydroxamic acid, and phenolic

Figure 11-5. Oxygen normally exchanges with the ferrous iron of deoxyhemoglobin (Eq. (1)). Oxygen can “capture” one of the iron electrons, resulting in the generation of methemoglobin (HgbFe³⁺) and superoxide (O₂⁻) (Eq. (2)). Superoxide must be detoxified or it can lead to oxidative injury within the cell. The pathways involved include superoxide dismutase (Eq. (3)), catalase (Eq. (4)), and glutathione peroxidase (Eqs. (5) and (6)). A supply of reduced glutathione (GSH) is necessary to prevent excessive oxidative injury.

compounds, a reactive ferryl (Fe⁴⁺) hemoglobin intermediate may be formed according to the following reaction:

In this intermediate, referred to as compound I, tyrosine may donate the extra electron, turning it into a reactive free radical. Compound I may undergo further reaction with organic compounds (AH₂ in the following equations) to yield additional free radicals according to the following reactions:

Hemoglobin contains exposed free cysteines (β93) that are critical for the structural integrity of the molecule. Oxidation of these groups can denature hemoglobin and decrease its solubility. The oxidized, denatured hemoglobin species comprise what has been designated sulfhemoglobin. The denatured hemoglobin can

form aggregates that bind to the cell membrane to form inclusions called *Heinz bodies*, a hallmark of oxidative injury to erythrocytes (Jandl, 1987). Heinz bodies can be visualized by use of phase contrast microscopy or supravital stains such as crystal violet. These membrane-associated inclusions impair the deformability of the erythrocyte membrane and thus impede movement of erythrocytes through the microcirculation and the spleen. Heinz bodies are effectively removed from the erythrocyte by the spleen, so they are not often observed in peripheral blood samples from patients despite ongoing oxidative injury. However, the culling of Heinz bodies can alter the morphology of the affected cells, giving rise to what are called “bite” cells and “blister” cells, which may provide an important clue as to the ongoing process (Yoo and Lessin, 1992). These cells look as though a portion of the cytoplasm had been cut away. Heinz body formation can be induced by in vitro exposure to oxidizing agents and patients with oxidative hemolysis often show increased in vitro formation of Heinz bodies.

Oxidative denaturation of the globin chain decreases its affinity for the heme group, which may dissociate from the globin chain during oxidative injury (Kumar and Bandyopadhyay, 2005). Free heme itself is toxic to cells and can induce tissue injury through formation of reactive oxygen species. The ferric iron in the heme ring may react with chloride to form a complex called hemin. Hemin is hydrophobic and intercalates into the erythrocyte membrane from which it is removed by interaction with albumin. However, if the rate of hemin formation exceeds the rate of removal by albumin, hemin accumulates in the membrane, where it can cause rapid lysis of the erythrocyte.

The generation of free radicals may also lead to peroxidation of membrane lipids (Jandl, 1987; Kumar and Bandyopadhyay, 2005). This may affect the deformability of the erythrocyte and the permeability of the membrane to potassium. The alteration of the Na⁺/K⁺ gradient is independent of injury to the Na⁺/K⁺ pump and is potentially lethal to the affected erythrocyte. Oxidative injury also impairs the metabolic machinery of the erythrocyte, resulting in a decrease in the concentration of ATP (Tavazzi *et al.*, 2000). Damage to the membrane can also permit leakage of denatured hemoglobin from the cell. Such free denatured hemoglobin can be toxic on its own. Free hemoglobin may irreversibly bind nitric oxide, resulting in vasoconstriction. Released hemoglobin may form nephrotoxic hemoglobin dimers, leading to kidney damage.

Oxidative injury thus results in a number of changes that decrease the viability of erythrocytes. Protection against many of the free radical-induced modifications is mediated by reduced glutathione (Njalsson and Norgren, 2005). Formation of reduced glutathione is dependent on NADPH and the hexose monophosphate shunt (Fig. 11-6). Significant oxidative injury usually occurs when the concentration of the xenobiotic is high enough (due to either high exposure or decreased metabolism of the xenobiotic) to overcome the normal protective mechanisms, or, more commonly, when there is an underlying defect in the protective mechanisms.

The most common enzyme defect associated with oxidative hemolysis is G-6-PD deficiency, a relatively common sex-linked disorder characterized by alterations in the primary structure of G-6-PD that diminish its functional activity (Beutler, 1996). It is often clinically asymptomatic until the erythrocytes are exposed to oxidative stress. The stress may come from the host response to infection or exposure to xenobiotics. The level of G-6-PD normally decreases as the erythrocytes age. In the African type of G-6-PD deficiency, the enzyme is less stable than normal; thus, the loss of activity is accelerated compared with normals. In the Mediterranean type of G-6-PD deficiency, the rate of loss of enzyme activity is even higher. Consequently, the older erythrocytes with the lowest

Table 11-6

Xenobiotics Associated with Oxidative Injury

Acetanilide	Phenylhydrazine
Naphthalene	Nitrobenzene
Nitrofurantoin	Phenacetin
Sulfamethoxypyridazine	Phenol
Aminosalicic acid	Hydroxylamine
Sodium sulfoxone	Methylene blue
Dapsone	Toluidine blue
Phenazopyridine	Furazolidone
Primaquine	Nalidixic acid
Chlorates	Sulfanilamide
Sulfasalazine	

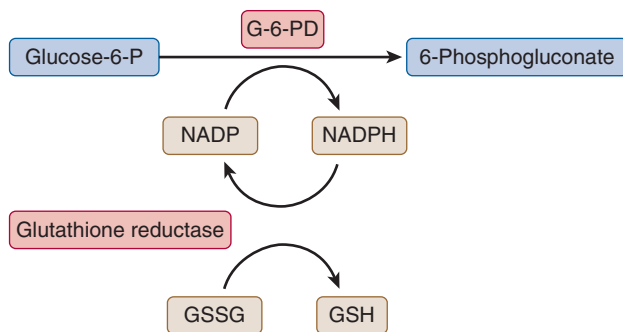

Figure 11-6. The hexose monophosphate shunt in the erythrocyte is critical for generation of NADPH, which helps maintain an intracellular supply of reduced glutathione (GSH). With a deficiency of glucose-6-phosphate dehydrogenase (G-6-PD), the rate-limiting step in this pathway, the cellular levels of GSH are reduced. Such cells show increased susceptibility to oxidative injury. Acute exposure of such cells to an oxidizing agent can result in rapid hemolysis.

levels of G-6-PD are most susceptible to hemolysis, with the degree of hemolysis affected by the residual amount of enzyme activity as well as the magnitude of the oxidative injury.

Erythrocyte-reduced glutathione is rapidly depleted on exposure to an oxidizing agent in patients with G-6-PD deficiency. This leads to the series of oxidative injuries described above with the development of intravascular and extravascular hemolysis. Oxidative hemolysis is usually reversible if the process is promptly recognized and the offending agent is removed. Occasionally the hemolysis may be sufficiently severe to result in death or serious morbidity (eg, renal failure). Hemolytic anemia may occur in patients with deficiency of glutathione synthetase due to the reduced intracellular concentration of glutathione (Njalsson and Norgren, 2005).

Nonoxidative Chemical-Induced Hemolysis Exposure to some xenobiotics is associated with hemolysis without significant oxidative injury (Beutler, 2006a,b,c). Arsenic hydride is a gas that is formed during several industrial processes. Inhalation of the gas can result in severe hemolysis, with anemia, jaundice, and hemoglobinuria. The mechanism of hemolysis in arsine toxicity is not understood. Lead poisoning is associated with defects in heme synthesis and a shortening of erythrocyte survival. The cause of the hemolysis is uncertain, but lead can cause membrane damage and interfere with the Na^+/K^+ pump. These effects may cause premature removal of erythrocytes from the circulation. Excess copper has been associated with hemolytic anemia. The pathogenesis may relate to inhibitory effects on the hexose monophosphate shunt and the Embden–Meyerhof pathway. Ingestion of excess chromium may result in hemolytic anemia and thrombocytopenia, although the mechanism is not known (Cerulli *et al.*, 1998). Significant hemolysis may also occur with biologic toxins found in insect and snake venoms (Beutler, 2006a,b,c).

Immune Hemolytic Anemia Immunologic destruction of erythrocytes is mediated by the interaction of IgG or IgM antibodies with antigens expressed on the surface of the erythrocyte. In the case of autoimmune hemolytic anemia the antigens are intrinsic components of the patient's own erythrocytes. A large number of drugs have been associated with enhanced binding of immunoglobulin to the erythrocyte surface and shortened RBC survival (Arndt and Garratty, 2005).

A number of mechanisms have been implicated in xenobiotic-mediated antibody binding to erythrocytes (Arndt and

Garratty, 2005). Some drugs, of which penicillin is a prototype, appear to bind to the surface of the cell, with the “foreign” drug acting as a *hapten* and eliciting an immune response. The antibodies that arise in this type of response only bind to drug-coated erythrocytes. Other drugs, of which quinidine is a prototype, bind to components of the erythrocyte surface and induce a conformational change in one or more components of the membrane. This type of interaction can give rise to a confusing array of antibody specificities. Some of the antibodies recognize only the *drug-membrane component* complex; others are specific for the membrane component, but only when drug is present; while still others may recognize the membrane component in the presence or absence of the drug. A third mechanism, for which α -methyl dopa is a prototype, results in production of a *drug-induced autoantibody* that cannot be distinguished from the antibodies arising in idiopathic autoimmune hemolytic anemia. The mechanism for induction of this group of antibodies is not understood, but may be related to development of an autoimmune response. A variant of this type of response is the augmentation of autoimmune hemolytic anemia that may occur during therapy of some lymphoproliferative disorders. Autoimmune phenomena, including autoimmune hemolytic anemia, are known to occur in lymphoproliferative disorders such as chronic lymphocytic leukemia (CLL). Treatment of these disorders with some drugs has been associated with worsening of the hemolytic anemia (Gonzalez *et al.*, 1998). It has been hypothesized that therapy further disrupts regulation of the autoimmune phenomenon, allowing increased antibody production.

Some xenobiotics are associated with *nonspecific deposition of proteins* on erythrocytes. This was first associated with cephalosporins but has also been seen with other drugs, including cisplatin and the β -lactamase inhibitors sulbactam and clavulanate (Arndt and Garratty, 2005). Immunoglobulin and complement proteins may be among the proteins deposited on the erythrocyte surface. These proteins may cause a positive direct antiglobulin test, suggesting a drug-induced antibody response. However, there is no evidence of a drug-dependent antibody in the patient's serum, and drug-treated erythrocytes may bind antibody from normal nondrug exposed serum. This form of antibody deposition is generally not associated with hemolysis, although the possibility of hemolysis related to this type of reaction has been raised.

Drug-induced intravascular hemolysis is often a dramatic clinical event and may be associated with fever, chills, back pain, hypotension, a rapid fall in hemoglobin concentration, a decrease in serum haptoglobin, a marked increase in serum LD, and hemoglobinuria (Arndt and Garratty, 2005). The clinical picture of extravascular hemolysis depends on the rate of hemolysis but is usually less dramatic. Often there is evidence of reticulocytosis, polychromasia, spherocytosis, a moderate increase in serum LD, and an increase in serum bilirubin. Serologic studies usually show evidence of IgG and/or complement on the surface of erythrocytes, although it may be difficult to document that antibody binding is drug-dependent. The mainstay of therapy in patients with drug-induced hemolytic anemia is removal of the offending agent and avoidance of reexposure.

TOXICOLOGY OF THE LEUKON

Components of Blood Leukocytes

The leukon consists of leukocytes, or white blood cells. They include granulocytes, which may be subdivided into neutrophils, eosinophils, and basophils; monocytes; and lymphocytes. Granulocytes and monocytes are nucleated ameboid cells that are

phagocytic. They play a central role in the inflammatory response and host defense. Unlike the RBC, which resides exclusively within blood, granulocytes and monocytes generally pass through the blood on their way to the extravascular tissues, where they reside in large numbers, although it is now understood that senescent neutrophils that remain in the circulation return to the bone marrow through the stromal-derived factor-1 (SDF-1) α /CXCR4 chemokine axis (Martin *et al.*, 2003).

Granulocytes are defined by the characteristics of their cytoplasmic granules as they appear on a blood smear stained with a polychromatic (Romanovsky) stain. Neutrophils, the largest component of blood leukocytes, are highly specialized in the mediation of inflammation and the ingestion and destruction of pathogenic microorganisms. The turnover of neutrophils is enormous and increases dramatically in times of inflammation and infection, elevating the number of these cells released from the bone marrow. Eosinophils and basophils modulate inflammation through the release of various mediators and play an important role in other homeostatic functions. All these are influenced by cellular and humoral immune responses, as discussed in greater detail in Chap. 12.

In the world of clinical and experimental toxicology, the neutrophil is the focus of concern when evaluating granulocytes as possible targets for drug and nontherapeutic chemical effects. Eosinophils and basophils are far more difficult to study, with changes in these populations most frequently associated with reactions to other target organ or systemic toxicity. Examples include the eosinophilia observed with the toxic oil syndrome that resulted from exposure to rapeseed oil denatured in aniline utilized in northwestern Spain (Kilbourne *et al.*, 1991), and the eosinophilia–myalgia syndrome associated with λ -tryptophan preparations contaminated with 1,1-ethylidene-bis[tryptophan] (Varga *et al.*, 1992). Peripheral eosinophilia is often but not reliably observed with hypersensitivity reactions to drugs (Roujeau, 2005), while tissue eosinophilia can be diagnostic, in the context of a suggestive clinical course, in conditions such as drug-induced cutaneous vasculitis (Bahrami *et al.*, 2006) and eosinophilic pneumonia (Flieder and Travis, 2004). This variability in systemic response can be genetically predisposed, as demonstrated in studies using transgenic mice on genetic restrictions in people afflicted by the aforementioned toxic oil syndrome (Gallardo *et al.*, 2005). The time course of the reaction can also influence whether eosinophilia can be demonstrated in hypersensitivity disease (Roujeau, 2005).

Evaluation of Granulocytes

The most informative test to assess the neutrophil compartment is the blood neutrophil count. Accurate interpretation requires an understanding of neutrophil kinetics and the response of this tissue to physiologic and pathologic changes. In the blood, neutrophils are distributed between *circulating* and *marginated* pools, which are of equal size in humans and in constant equilibrium (Athens *et al.*, 1961). A blood neutrophil count assesses only the circulating pool, which remains between 1800 and 7500/ μ L in a healthy adult human (Dale, 2006).

This constancy is remarkable, considering that as many as 10^{11} neutrophils are released from the marrow daily, that this circulating pool represents only 1% of the total body neutrophils (Semerad *et al.*, 2002), and that the circulating half-life of these cells is only approximately six hours (Cartwright *et al.*, 1964). How this extraordinary regulation is achieved is only partially understood. Studies using knockout mice suggest that G-CSF is an essential regulator of both granulopoiesis and neutrophil release

from the bone marrow (Semerad *et al.*, 2002). It is induced by the T-cell-derived cytokine IL-17 that, in turn, is controlled by IL-23 that is provided by dendritic cells and macrophages (Stark *et al.*, 2005). The latter is downregulated by the phagocytosis of apoptotic neutrophils in the tissues, which provides an important negative feedback loop. The upregulation and downregulation of chemokine receptors further controls the release of neutrophils from the bone marrow (as discussed below) and their return following senescence (Martin *et al.*, 2003). Pharmaceutical companies are currently developing recombinant proteins that function as agonists and inhibitors of these mediators, which have great potential as exciting new therapies. Many will also be shown to cause unacceptable immunotoxicity and hematotoxicity, which portends exciting times for the academic and industrial hematopathologist and toxicologist.

Neutrophil kinetics and response to disease will vary substantially among animal species (Feldman *et al.*, 2006). Thus, a thorough understanding of these features in any animal model used in investigative toxicology is required before informed interpretations can be made. In humans, clinically significant neutropenia occurs when the blood neutrophil count is less than 1000/ μ L, but serious recurrent infections do not usually occur until counts fall below 500/ μ L (Dale, 2006). Morphologic assessment of peripheral blood granulocytes can be helpful in characterizing neutropenia. In humans and most healthy animal species, mature (segmented) and a few immature (band) neutrophils can be identified on blood films stained with Wright or Giemsa stain. During inflammation, a “shift to the left” may occur, which refers to an increased number of immature (nonsegmented) granulocytes in the peripheral blood, which may include bands, metamyelocytes, and occasionally myelocytes. During such times, neutrophils may also show “toxic” granulation, Döhle bodies, and cytoplasmic vacuoles. These morphologic changes may be prominent in sepsis or as a result of drug or chemical intoxication. In order to fully characterize such changes or understand the pathogenesis of the abnormality, bone marrow must be examined using marrow aspirates and biopsies. These provide information on rates of production, bone marrow reserves, and abnormalities in cell distribution, and occasionally specific clues as to etiology. In vitro stem cell assays may be used to assess the granulocyte progenitor cell compartment, which may include colony-forming-units granulocyte/monocyte (CFU-GM) performed in a semisolid medium, such as agar or methylcellulose, which contains appropriate growth factors, as discussed later in this chapter. Normal human marrow specimens contain approximately 50 to 1000 CFU-GM per 10^6 nucleated cells cultured (Liesveld and Lichtman, 1997). Marrow stem cell reserves can be assessed in vitro after administration of G-CSF (Demirer and Bensinger, 1995), which stimulates increased production and release of neutrophil precursors. Glucocorticoids (Peters *et al.*, 1972) and epinephrine (Babior and Golde, 1995) may also be used for this purpose but are rarely used in a clinical setting.

The recent understanding that the CXC chemokine ligand SDF-1/CXCR4 mediates the retention of granulopoietic stem cells within their bone marrow niche (Laurence, 2006; Sharma *et al.*, 2011), as well as mature neutrophils within the bone marrow pool (Semerad *et al.*, 2002), has led to the development of an inhibitor of this ligand that, when administered with G-CSF, can cause a transient release of neutrophils and CD34+ (stem) cells into the circulation (Liles *et al.*, 2005). The latter can be collected and re-engrafted to form new functioning bone marrow (Broxmeyer *et al.*, 2005). The homing and retention of such hematopoietic stem/progenitor cells is influenced by complex and highly coordinated interactions among adhesion molecules, cytokines, growth

factors, and regulatory cofactors that are only partially understood (Sharma *et al.*, 2011). The ability to manipulate this system, as in the above experiments and through the many recombinant proteins under development, will continue to provide important research, diagnostic, and therapeutic tools for the hematologist, oncologist, and toxicologist.

The degree of proliferation in the granulocyte compartment can also be assessed using older techniques that employ ^3H -thymidine suicide assays or DNA-binding dyes with fluorescence-activated cell sorting analyses (Keng, 1986).

Toxic Effects on Granulocytes

The toxicologist is concerned with the effect of xenobiotics on granulocytes as relates to proliferation (granulopoiesis) and kinetics, the extent to which a drug or chemical contaminant can impair the vital functions these cells perform, and how neutrophils mediate or exacerbate inflammatory disease or other target organ toxicity. The last two areas are discussed in Chap. 12, as they relate to their role as important effector cells of the immune system. However, it is difficult to separate effects on granulopoiesis and neutrophil kinetics from that of function. Both are complex and highly regulated, as discussed above, through an array of growth factors, chemokines, cytokines, and interactions with monocytes, dendritic cells, and lymphocytes in a bidirectional, multicompartmental manner (Nathan, 2006). Such complexity is not surprising, given the daunting task these cells perform, which is elegantly described in a review by Nathan (2006): “The [neutrophil] must remain non-sticky as it hurtles through the arterial and arteriolar circulation; then it must squeeze through capillaries smaller in diameter than itself, without allowing collision, friction, or distortion to activate it. A fraction of the population must adhere tightly enough to the normal endothelium of post-capillary venules to resist being washed away in the circulation, but loosely enough to roll while scouting for evidence of tissue damage and microbial infection. If such evidence is received, the cell must crawl to a boundary between endothelial cells, penetrate the junctions and the underlying basement membrane without damaging these structures, move up the chemotactic gradient, and decide whether its original information remains valid. If the answer is negative, the cell must execute itself by apoptosis. If the answer is positive, the cell must attempt to engulf and destroy microbes. If it cannot locate microbes quickly, it must attempt to destroy them at a distance by releasing every weapon at its disposal.” Many of the mediators and interactions that enable this feat have now become targets for the therapeutic dysregulation of these processes, which has led to the development of candidate drugs that may prove to be uniquely efficacious and/or toxic, as discussed below.

Effects on Proliferation and Kinetics As with other hematopoietic tissue, the high rate of proliferation of neutrophils makes their progenitor and precursor granulocyte pool particularly susceptible to inhibitors of mitosis. Such effects by cytotoxic drugs are generally nonspecific, as they similarly affect cells of the dermis, gastrointestinal tract, and other rapidly dividing tissues. Agents that affect both neutrophils and monocytes pose a greater risk for toxic sequelae, such as infection (Dale, 2006). Such effects tend to be dose-related, with mononuclear phagocyte recovery preceding neutrophil recovery (Arneborn and Palmblad, 1982).

Myelotoxicity in clinical medicine and preclinical safety studies today is most commonly seen with cytoreductive cancer chemotherapy agents. However, this is changing, as more cancer cell-targeted, normal-tissue-sparing anticancer agents are being

developed. In fact, most published reviews today on drug-induced neutropenia and agranulocytosis do not even address that associated with such cytotoxic agents. Accordingly, the term commonly refers to *idiosyncratic reactions*, most often secondary to accelerated immune-mediated destruction of neutrophils and their progenitors, as discussed below. The toxicity associated with cytotoxic drugs, however, remains important in that it is often dose-limiting (even with some of the newer drugs) with serious manifestations that include febrile neutropenia associated with life-threatening infections (Kuderer *et al.*, 2002). These drugs vary in terms of their mechanism, the kinetics of the cytopenias they induce, and how individual patients or animals respond. Most act to inhibit DNA synthesis or directly attack its integrity through the formation of DNA adducts or enzyme-mediated breaks (Chabner *et al.*, 2006). While cytoreductive drugs such as alkylating agents, cisplatin, and nitrosureas can be toxic to both resting and actively dividing cells, nonproliferating cells such as metamyelocytes, bands, and mature neutrophils are relatively resistant (Friberg and Karlsson, 2003). Generally, stem cells cycle slowly and are therefore minimally affected by a single administration of a cytotoxic drug such as 5-fluorouracil; however, such exposure can stimulate cycling activity, making these cells more vulnerable to doses administered three to five days later (Harrison and Lerner, 1991). Cytokines have long been thought to enhance these effects by driving cells into the S phase (Smith *et al.*, 1994). Sustained exposure to drugs affecting slowly cycling stem cells is believed to cause more prolonged myelosuppression, similar to that observed with idiosyncratic toxic neutropenia (Tannock, 1986). Recent studies suggest that these features are shared by cancer stem cells, which is the basis for the more sophisticated cancer interventions and regimens under development today (Eramo *et al.*, 2008; Vermeulen *et al.*, 2010; Ricci-Vitiani *et al.*, 2010).

Finally, there is considerable variation among individuals as regards susceptibility to bone marrow toxicity; this can relate to how the drug is metabolized as with 5-fluorouracil (Sundman-Engberg *et al.*, 1998) and 6-mercaptopurine (Chabner *et al.*, 2006), gender (Huang *et al.*, 2007; Gamazon *et al.*, 2011), and other factors. Based on these and other data, including plasma drug concentrations, “semi-mechanistic” pharmacokinetic/pharmacodynamic models of myelosuppression have been developed to tailor doses and treatment regimens to individual patients (Friberg and Karlsson, 2003). Pharmacokinetic monitoring is now routinely performed with some anticancer treatment regimens, particularly high-dose methotrexate (Chabner *et al.*, 2006).

Two innovations have had a dramatic impact on cancer chemotherapy and the dose-limiting myelotoxicity associated with these drugs: (1) the aforementioned development of drugs with cancer cell-specific molecular targets that are relatively bone marrow sparing, such as those that target aberrant growth factor receptor signaling, apoptosis, angiogenesis, and other metabolic, immune, inflammatory, and mutation-promoting pathways that selectively advantage tumor cells (Hanahan and Weinberg, 2011); and (2) the use of hematopoietic growth factors, the cotreatment with which mitigates or successfully rescues patients from the effects of myelosuppression (Andres *et al.*, 2010). Most notable of the latter has been the development and application of the G-CSFs filgrastim and the longer acting pegfilgrastim, the action of which was discussed previously. Treatment with these recombinant proteins can substantially reduce the incidence, severity, and duration of neutropenia and its complications (Rader, 2006). Antagonists to the aforementioned chemokine ligand CXCR4 are also under development for treatment alone or in combination with G-CSF, which have been shown to be effective in

mobilizing both stem cells and mature neutrophils (De Clercq, 2005; Larochelle *et al.*, 2006). Cytokine-induced differentiation therapy of leukemias is another exciting treatment modality (Leung *et al.*, 2005). The prospect of exaggerated pharmacology and off-target effects of these sophisticated interventions should provide the preclinical toxicologist and oncologist with interesting hematotoxicologic challenges.

Lindane, an insecticide used to treat seeds and soil, has been associated with leukopenia (Parent-Massin *et al.*, 1994). It is cytotoxic for human CFU-GMs at concentrations observed in blood and adipose tissue from exposed human subjects. An example of chemicals affecting mature cells is methyl methacrylate monomer, which has been used in orthopedic surgical procedures and is cytotoxic to both neutrophils and monocytes at clinically relevant concentrations (Dahl *et al.*, 1994).

Chemicals that affect granulocyte kinetics can cause neutropenia or neutrophilia that has variable toxicologic significance. The effects of epinephrine and glucocorticoids on granulocyte kinetics were discussed previously. Dexamethasone has long been known to cause neutrophilia through enhanced release of mature neutrophils from the bone marrow and demargination, with the latter being the largest contributor to the expanded circulating pool (Nakagawa *et al.*, 1998). It is now clear that the reduced margination of neutrophils is mediated by multiple effects, including altered chemotaxis, expression of adhesion molecules, and the release of mediators from other cells (Barnes, 2006; Caramori and Adcock, 2005). It is widely assumed that inhibition of margination and homing are among the important mechanisms of the anti-inflammatory and immunosuppressive effects of these widely used drugs. The development of drugs with more selective effects on neutrophils is among the most active areas of investigative pharmacology and toxicology today.

Inhibitors of the CXC chemokine ligands such as CXCR4 are under development as anticancer drugs and often associated with transient neutropenia (unpublished data). The commonly observed (yet remarkable) late-onset neutropenia (LAN) following treatment with rituximab, an anti-CD20 monoclonal antibody used to treat CD20-positive lymphoma and rheumatoid arthritis, is a good example of a common drug-induced neutropenia—in this case, typically self-limiting and thought to be of limited clinical significance. Informed hypotheses on the mechanism of LAN include perturbations of granulocyte homeostasis, mediated by the complex interaction between B-cell recovery and SDF-1 (Grant *et al.*, 2011) and polymorphisms in immunoglobulin Fc receptor genotypes, which enhance ADCC by rituximab, resulting in increased killing of malignant and normal B cells. The latter could lead to the release of lysosomal enzymes and the destruction of neutrophils as “bystanders” (Hincks *et al.*, 2011). Consistent with these hypotheses is the recent observation of LAN being a good prognostic indicator in lymphoproliferative disorders (Hincks *et al.*, 2011).

Effects on Function While there are a variety of disorders associated with defects in the parameters of neutrophil function discussed above, demonstrable *in vivo* effects associated with drugs and nontherapeutic chemicals are surprisingly few (Borregaard and Boxer, 2006). Examples include ethanol and glucocorticoids, which impair phagocytosis and microbe ingestion *in vitro* and *in vivo* (Brayton *et al.*, 1970). Iohexol and ioxaglate, components of radiographic contrast media, have also been reported to inhibit phagocytosis (Lillevang *et al.*, 1994). Superoxide production, required for microbial killing and chemotaxis, has been reported to be reduced in patients using parenteral heroin as well

as in former opiate abusers on long-term methadone maintenance (Mazzone *et al.*, 1994).

In addition to glucocorticoids, several drugs and nontherapeutic chemicals have been shown to inhibit neutrophil chemotaxis. Examples include macrolide antibiotics, which suppress the expression of the adhesion molecule ICAM (Tamaoki, 2004); zinc salts, which are found in antiacne preparations (Dreno *et al.*, 1992); the insecticide chlordane (Miyagi *et al.*, 1998); and mercuric chloride/methylmercuric chloride (Contrino *et al.*, 1988). More common is the activation of neutrophils with the potential for proinflammatory consequences, specifically through increased phagocytosis, O_2^- production, or both. Examples include the environmental contaminants sodium sulfite, mercuric chloride, chlordane, and toxaphene (Girard, 2003). This toxicologic potential of xenobiotics will be discussed in more detail in Chap. 12.

Idiosyncratic Toxic Neutropenia Of greater concern are chemicals that unexpectedly damage neutrophils and granulocyte precursors—particularly to the extent of inducing *agranulocytosis*, which is characterized by a profound depletion in blood neutrophils to less than 500/ μ L (Pisciotta, 1973). The term was first used by Schultz in 1922 in patients with severe sore throat associated with a marked reduction of granulocytes, followed by sepsis and death (Schultz, 1922). Drug association was first demonstrated through rechallenge experiments performed on two patients with aminopyrine-induced agranulocytosis, who developed leucopenia within two hours of reexposure (Madison and Squier, 1934). A later study demonstrated that blood transferred from an agranulocytosis patient to normal controls resulted in a rapid drop in neutrophil count, suggesting a role for a preformed blood factor(s) such as antibodies (Moeschlin and Wagner, 1952). Such toxicity occurs in specifically conditioned individuals, and is therefore termed “idiosyncratic.” While rare, the seriousness of this disorder, as with aplastic anemia, makes it among the most important hematotoxicities, as regards regulatory scrutiny and risk:benefit considerations, which justifies the detailed discussion below. Acute agranulocytosis is attributed to drugs in >70% of cases (Garb, 2007).

Mechanisms of idiosyncratic damage often do not relate to pharmacologic properties of the parent drug, which makes managing this risk a particular challenge to hematologists and toxicologists, as discussed later in this chapter. Preclinical toxicology is rarely predictive of these effects, which are generally detected and characterized following exposure of a large population to the drug (Dieckhaus *et al.*, 2002; Szarfman *et al.*, 2002). Idiosyncratic drug-induced neutropenia may be dose-related and involve a nonselective disruption of protein synthesis or cell replication resulting in agranulocytosis, as discussed below. Alternatively, and more commonly, it may not be dose-dependent (as qualified below), in which case it is usually thought to be allergic or immunologic in origin. The latter has been observed with many drugs, and is more frequently observed in women, older patients, and patients with a history of allergies (Dale, 2006).

Idiosyncratic xenobiotic-induced agranulocytosis may involve a sudden depletion of circulating neutrophils concomitant with exposure, which may persist as long as the chemical or its metabolites persist in the circulation. Hematopoietic function is usually restored when the agent is detoxified or excreted. Suppression of granulopoiesis, however, is more prevalent than peripheral lysis of neutrophils and is asymptomatic unless sepsis supervenes (Pisciotta, 1973). The onset of leukopenia in the former is more gradual, but may be precipitous if lysis of circulating neutrophils also occurs. The pattern of the disease varies with the stage of granulopoiesis affected, which has been well defined for several drugs that cause

Table 11-7

Stages of Granulocytopoiesis: Site of Xenobiotic-Induced Cellular Damage

STAGE OF DEVELOPMENT	DISEASE	OFFENDING DRUGS
Uncommitted (totipotent) stem cell CFU-S	Aplastic anemia	Chloramphenicol Gold salts Phenylbutazone Phenytoin Mephenytoin Carbamazepine
Committed stem cell CFU-G CFU-E BFU-E	Aplastic anemia Agranulocytosis Pure red cell aplasia	Carbamazepine Chlorpromazine Carbamazepine Clozapine Phenytoin
Morphologically recognizable precursors	Hypoplastic marrow	Most cancer chemotherapy agents
Dividing pool Promyelocyte Myelocyte	Hypoplastic marrow	Chloramphenicol Alcohol
Nondividing pool Metamyelocytes, bands PMNs	Agranulocytosis	Clozapine Phenothiazines, etc
Peripheral blood lysis PMNs	Agranulocytosis	Clozapine, etc Aminopyrine

bone marrow toxicity (Table 11-7). Toxicants affecting uncommitted stem cells induce total marrow failure, as seen in aplastic anemia, which generally carries a worse prognosis than chemicals affecting more differentiated precursors, such as CFU-G. It is thought that, in the latter case, surviving uncommitted stem cells eventually produce recovery, provided that the risk of infection is successfully managed during the leukopenic episodes (Pisciotta, 1973).

The incidence of drug-induced idiosyncratic agranulocytosis ranges from 2 to 15 cases per million patients exposed to drugs per year (Andres *et al.*, 2002). While all drugs may be causative, the most commonly incriminated drugs include antithyroid agents and antibiotics, particularly sulfonamides (Andres *et al.*, 2002; Berliner *et al.*, 2004). An extensive case-control study on drug-induced agranulocytosis in Barcelona, Spain, followed 177 community cases (representing 78.73 million person-years), which were compared with 586 sex-, age-, and hospital-matched control subjects previously treated with the same putative drugs (Ibanez *et al.*, 2005). The annual incidence was 3.46:1 million, which increased with age. The fatality and mortality rates were 7.0% and 0.24:1 million, respectively. The drugs most frequently implicated (in decreasing order of odds ratio) were ticlopidine hydrochloride, calcium dobesilate, antithyroid drugs, dipyrone, and spironolactone. Other drugs associated with significant risk were pyrithyldione, cinepazide, aprindine hydrochloride, carbamazepine, sulfonamides, phenytoin and phenytoin sodium, β -lactam antibiotics, erythromycin stearate and erythromycin ethylsuccinate, and diclofenac sodium. These drugs accounted for 68.6% of all cases. Some drugs commonly implicated in the past, such as phenylbutazone, chloramphenicol, and ticlopidine, are used less commonly today due to this and other toxicity. Curiously, the incidence of this idiosyncratic reaction has not

changed in the western hemisphere over the past 30 years, despite this evolution of putative drugs, suggesting that host factors are critical in the pathogenesis of the toxicity (Tesfa *et al.*, 2009).

The severity of the neutropenia often causes severe sepsis or localized infections, such as sore throat, pneumonia, or various cutaneous infections. Prior to the use of hematopoietic growth factors, the mortality was 10% to 20% (Julia *et al.*, 1991); with appropriate management it is now less than 5% (Andres *et al.*, 2010).

Clozapine-induced agranulocytosis is unique, as a genetic predisposition has been established (Turbay *et al.*, 1997; Yunis *et al.*, 1995). Prior to an aggressive risk management program that included careful screening of prospective patients and early detection through hematologic monitoring, the incidence of agranulocytosis with this highly efficacious atypical antipsychotic was as high as 1% to 2%. This measure reduced the incidence to 0.38% and the mortality by 90% (Honigfeld *et al.*, 1998).

Mechanisms of Toxic Neutropenia Because cases of drug-induced neutropenia are relatively rare, sporadic, or transient, studies on the pathogenesis of this hematotoxicity have been limited. Toxic neutropenia has historically been classified according to mechanism as *immune-mediated* or *nonimmune-mediated*. There has long been a debate in the literature as to whether the principal mechanism of idiosyncratic drug-induced neutropenia (including agranulocytosis) is immune-mediated, or subsequent to the generation of toxic metabolites—both involving “preconditioning” through genetically determined immune responses to, or metabolism of, the putative drug, respectively. Both are consistent with the aforementioned early observations of Madison and Squier (1934) where transfusion of blood from affected patients to normal

subjects induced neutropenia, presumably involving a humoral factor—presumably an antibody. There is now consensus that the mechanism of most drug-induced idiosyncratic diseases, including hepatotoxicity, Stevens–Johnson syndrome, agranulocytosis, and aplastic anemia, usually is immune-mediated, often involving altered proteins through reactive metabolite-mediated damage (Zhang *et al.*, 2011). The Th-17 T lymphocyte is emerging as an important mediator of this through a cellular immune mechanism demonstrated in aplastic anemia (de Latour *et al.*, 2010; Plataniias, 2010). Two hypotheses as to the mechanism (or alternative pathogenesis) for these idiosyncratic reactions that have emerged based on observations over the past 10 years include the *hapten hypothesis* and the *danger hypothesis* (Zhang *et al.*, 2011). The former involves a reactive metabolite binding to a protein making it “foreign,” which in turn induces an immune response that leads to the toxicity. The latter has a reactive metabolite damaging a cell, which elicits an immune response against the drug or an autoimmune response. The “perfect storm” in the rare individual in which these reactions occur is thought to be caused by preconditioned (or individual-specific) circumstances that drive both the metabolism of the drug and the immune reactions to the altered proteins. Consistent with these hypotheses is the fact that aplastic anemia and the more common agranulocytosis can be induced by many of the same drugs, most of which can be oxidized to reactive metabolites by the myeloperoxidase system of neutrophils, macrophages, and/or their precursors (Utrecht, 1990).

The incidence of xenobiotic-induced immune neutropenia is considerably less than that of immune hemolytic anemias (Vandendries and Drews, 2006). In immune-mediated neutropenia, antigen–antibody reactions lead to destruction of peripheral neutrophils, granulocyte precursors, or both. As with RBCs, an immunogenic xenobiotic can act as a hapten, where the chemical must be physically present to cause cell damage, or may induce immunogenic cells to produce antineutrophil antibodies that do not require the drug to be present (Salama *et al.*, 1989). Also like immune hemolytic anemia, drug-induced *autoimmune* neutropenia has been observed (Capsoni *et al.*, 2005). Examples of drugs that have been implicated include fludarabine (Stern *et al.*, 1999), propylthiouracil (Sato *et al.*, 1985), and rituximab (Voog *et al.*, 2003). Xenobiotic-induced immune-mediated damage may also be cell-mediated (Pisciotta, 1973).

Detection of xenobiotic-induced neutrophil antibodies is also considerably more difficult than that of RBCs or platelets. This is because the neutrophil is relatively fragile and short-lived, and becomes easily activated (Palmlad *et al.*, 2001). There is no good test for direct antigranulocyte antibodies comparable to the Coombs (antiglobulin) test. Several assays have been used, which can be grouped into four categories: those measuring end points of leukoagglutination, cytotoxic inhibition of neutrophil function, immunoglobulin binding, and those using cell-mediated mechanisms. Among the specific challenges these assays pose are the tendency of neutrophils to stick to each other *in vitro*, attract immunoglobulin nonspecifically to their surface, and reflect membrane damage through indirect and semiquantitative changes (Pisciotta, 1973). Most neutrophil-associated antibody assays applied clinically today employ flow cytometry, with the indirect granulocyte immunofluorescence test being the most promising (Sella *et al.*, 2010). The reader is referred elsewhere for a more detailed discussion of assays for immune-mediated neutrophil damage (Hagen *et al.*, 1993; Nifi *et al.*, 2006; Palmlad *et al.*, 2001; Sella *et al.*, 2010).

Some nonimmune-mediated toxic neutropenias have long been known to have a genetic predisposition (Pisciotta, 1973). Direct damage may cause inhibition of granulopoiesis or neutrophil

function. It may entail failure to detoxify or excrete a xenobiotic or its metabolites, which subsequently build up to toxic proportions (Gerson and Meltzer, 1992; Gerson *et al.*, 1983; Utrecht, 1990). Some studies suggest that a buildup of toxic oxidants generated by leukocytes can result in neutrophil damage, as with the reactive intermediates derived from the interaction between clozapine and neutrophils. The resulting superoxide and hypochlorous acid production by the myeloperoxidase system are thought to contribute to clozapine-induced neutropenia (Utrecht, 1990). Accumulation of nitrenium ion, a metabolite of clozapine that causes a depletion of ATP and reduced glutathione, rendering the neutrophil highly susceptible to oxidant-induced apoptosis, is now thought to be the principal mechanism of this disorder (Williams *et al.*, 2000).

Examples of agents associated with immune and nonimmune neutropenia/agranulocytosis are listed in Table 11-8.

LEUKEMOGENESIS AS A TOXIC RESPONSE

Human Leukemias

Leukemias are proliferative disorders of hematopoietic tissue that are monoclonal in origin and thus originate from individual bone marrow cells. Historically they have been classified as myeloid or lymphoid, referring to the major lineages for erythrocytes/granulocytes/thrombocytes or lymphocytes, respectively. Because the degree of leukemic cell differentiation has also loosely correlated with the rate of disease progression, poorly differentiated phenotypes have been designated as “acute,” whereas well-differentiated ones are referred to as “chronic” leukemias. The classification of human leukemias proposed by the French–American–British (FAB) Cooperative Group, based on the above and other morphologic features (Bennett and Sanger, 1982; Bennett *et al.*, 1985; Levine and Bloomfield, 1992), has largely been replaced by the

WHO classification. The WHO classification of acute myelogenous leukemia (AML) incorporates some of the traditional features associated with AML subtyping while placing increasing significance on molecular features, particularly recurrent cytogenetic abnormalities such as t(8;21), inv(16), t(15;17), and 11q23. The revised *WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues* provides the most up-to-date diagnostic framework for classifying CLL, chronic myelogenous leukemia (CML), acute lymphoblastic leukemia (ALL), AML, myeloproliferative neoplasms (MPN), and the myelodysplastic syndromes (MDS), along with various subtypes of these disorders (Swerdlow *et al.*, 2008). The result of the WHO classification is that hematologic diseases that are biologically homogenous are subtyped, leading to greater prognostic and therapeutic relevance (Altucci *et al.*, 2005). These early correlations imply that the biology and clinical features of these proliferative disorders relate to the stage of differentiation of the target cell, which is now being linked to individual gene alterations, as well as epigenetic factors such as cytokine stimulation (Altucci *et al.*, 2005; Look, 2005).

There is considerable evidence supporting the notion that leukemogenesis is a multievent progression (Look, 2005; Pedersen-Bjergaard *et al.*, 1995; Varmus and Weinberg, 1993; Vogelstein *et al.*, 1988; Williams and Whitaker, 1990). These studies suggest that factors involved in the regulation of hematopoiesis also influence neoplastic transformation. Such factors include cellular growth factors (cytokines), proto-oncogenes, and other growth-promoting genes, as well as additional genetic and epigenetic factors that govern survival, proliferation, and differentiation.

Secondary leukemia is a term used to describe patients with AML or MDS who have a history of environmental, occupational, or therapeutic exposure to hematotoxins or radiation. It also includes patients with AML evolving from antecedent myelodysplastic or other myeloid stem cell disorders. *Therapy-related AML and MDS* is a term applied to the former group; both are used to distinguish from features of AML that arise de novo. Various cytogenetic findings have been associated with prognosis and response to therapy. It has been suggested that secondary leukemias be redefined as any leukemia with a specific cytogenetic or molecular poor prognostic feature due to a presumed predisposing factor (Rowe, 2002). While it is generally accepted that the incidence of secondary AML is increasing, the true incidence remains unknown (Preiss *et al.*, 2010).

Mechanisms of Toxic Leukemogenesis

The understanding that certain chemicals and radiation can dysregulate hematopoiesis, resulting in leukemogenesis, is a relatively recent one. While suggested by Hunter as early as 1939, following his observations on benzene exposure and AML (Hunter, 1939), it was not until the introduction of radiation and chemotherapy as treatments for neoplasia that these agents became associated with blood dyscrasias that included (or led to) AML (Andersen *et al.*, 1981; Casciato and Scott, 1979; Foucar *et al.*, 1979). The notion emerged that myelotoxic agents, under certain circumstances, can be leukemogenic.

Curiously, AML is the dominant leukemia associated with drug or chemical exposure, followed by MDS (Andersen *et al.*, 1981; Casciato and Scott, 1979; Irons, 1997). The evidence that this represents a continuum of one toxic response is compelling (Irons, 1997; Look, 2005). This has also been linked to cytogenetic abnormalities, particularly nonrandom deletions that include 7q⁻, 5q⁻, 20q⁻, 6q⁻, 11q⁻, and 13q⁻, which activate tumor suppressor genes required for normal myeloid cell development (Bench *et al.*, 1998), as well as translocations implicating the mixed lineage leukemia (MLL) gene located in the 11q23 region. Monosomal karyotype, including that for 5 and 7, together with the latter translocations, is associated with a highly adverse prognosis in secondary AML like those following treatment of acute promyelocytic leukemia (Sanz and Montesinos, 2011). The frequency of at least one of the aforementioned deletions in patients who develop MDS and/or AML after treatment with alkylating or other antineoplastic chemicals has historically run from 67% to 95%, depending on the study (Bitter *et al.*, 1987; Johansson *et al.*, 1991; Le Beau *et al.*, 1986; Pedersen-Bjergaard *et al.*, 1984; Rowley *et al.*, 1981). The cytogenetic classification known as *complex karyotypes*, or complex chromosomal aberrations (CCAs, defined as more than three aberrations), has been shown to occur in up to 50% of therapy-related AML and MDS cases (Mauritzson *et al.*, 2000; Rossi *et al.*, 2000). CCAs are also associated with the most unfavorable prognosis among the subtypes of MDS and AML (Look, 2005). These observations, together with the understandings on the pathogenesis of leukemia previously discussed, have further corroborated the model proposed by Irons 15 years ago for the evolution of toxic leukemogenesis, which is illustrated in Fig. 11-7 (Irons, 1997).

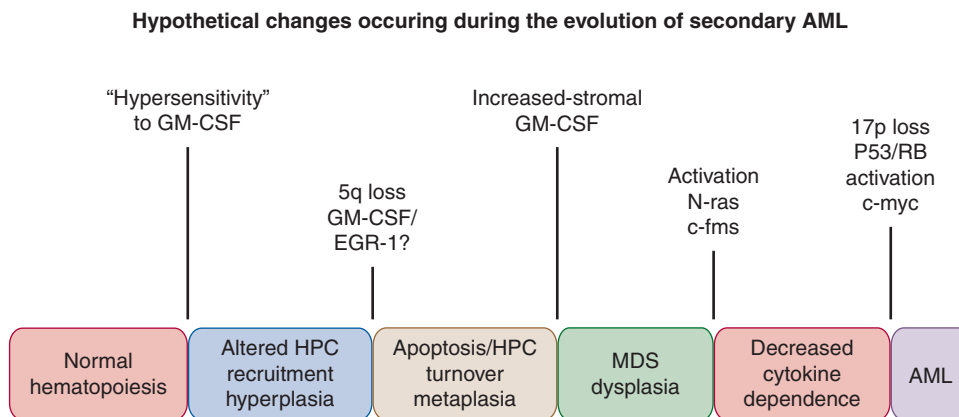

Figure 11-7. Hypothetical model for the evolution of *s*-AML involving 5q⁻. Schematic representation of one model for tumor progression consistent with frequently observed events in the development of AML secondary to drug or chemical exposure. Altered myeloid progenitor cell proliferation leads to increased division in the target cell population, which results in clonal loss of heterozygosity due to nondysjunction (eg, 5q⁻). The resulting haploinsufficiency of a gene, such as GM-CSF, results in increased cell turnover, abnormal maturation, and ineffective hematopoiesis (ie, MDS) in the abnormal clone. This is subsequently followed by activation of additional proto-oncogenes that result in progressive growth and survival independence in successive subclones and the development of overt AML. (Adapted from Irons (1997), with permission from Elsevier Science.)

The relatively low frequency of deletions in chromosomes 5 and 7 thought to occur in de novo, as compared with secondary AML, has led to using these cytogenetic markers to discriminate between toxic exposures and other etiologies of this leukemia. However, a recent population-based cytogenetic study of adult secondary AML and age- and sex-matched de novo AML patients showed that, with the exception of monosomy 7, the distributions of chromosomal abnormalities among the groups were comparable (Preiss *et al.*, 2010). The same study found a higher degree of genetic instability in the therapy-related AML patients, compared with secondary AML that evolved from antecedent stem cell disorders such as MDS, which was characterized by a more frequent combination of numerical and structural aberrations, complex karyotypes, abnormal mitoses only, and hypodiploidy.

Larson and LeBeau reported the results of cytogenetic analyses on 306 consecutive patients with therapy-related AML, which were largely consistent with the above understandings (Larson and Le Beau, 2005; Look, 2005). They went on, however, to perform gene expression profiling of CD34+ hematopoietic progenitor cells from these patients, through which they were able to identify distinct subtypes of AML with characteristic gene expressions. Not surprisingly, these early progenitor cells showed expression patterns typical of arrested differentiation. Through this work they positioned therapy-related AML as an important model that provides a unique opportunity to examine the effects of mutagens on carcinogenesis in humans, as well as the role of genetic susceptibility. The fact that therapy-related AML behaves differently than the de novo disease with the same chromosomal abnormalities suggests that there is indeed a fundamental difference on the genetic level. Tools such as next-generation transcriptome sequencing are now being used to identify perturbations in genetic and molecular pathways that are unique to therapy-related leukemias, which will have implications for interventions with the new sophisticated targeted agents under development today (Stoddart *et al.*, 2011).

Some of the same chromosomal deletion changes described with therapy-related AML have been observed in AML patients occupationally exposed to benzene (Bitter *et al.*, 1987; Cuneo *et al.*, 1992; Fagioli *et al.*, 1992; Golomb *et al.*, 1982; Mitelman *et al.*, 1978, 1981), who also show aneuploidy with a high frequency of involvement of chromosome 7 (Irons, 1997). However, more recent evidence suggests that chromosomes 5 and 7 are not preferential targets in benzene-related cases, which is consistent with the fact that benzene metabolites are actually very weak alkylating agents (Pyatt and Thirman, 2011). Molecular mechanisms for benzene-induced hematotoxicity, which include both leukemogenesis and aplastic anemia (Hoffmann *et al.*, 2001), are thought to include the bioactivation of reactive metabolites (Powley and Carlson, 2001), the formation of reactive oxygen species (Kolachana *et al.*, 1993), and activation of the aryl hydrocarbon receptor (AhR) and the oncogene C-Myb (Wan *et al.*, 2005). Studies have also suggested that polymorphisms in genes involved in DNA double strand break repair might influence susceptibility to these effects (Shen *et al.*, 2006).

Other forms of leukemia—including CML, CLL, ALL, and multiple myeloma—have shown weak correlations with occupational exposure or treatment with alkylating agents (Irons, 1997). The latter has been repeatedly associated with exposure to benzene, although a causal relationship has yet to be demonstrated (Bergsagel *et al.*, 1999).

Leukemogenic Agents

The overwhelming majority of toxic or secondary leukemias seen today are therapy-related (Godley and Larson, 2001), due, in part,

to stricter workplace and environmental regulations that have limited exposure to potential carcinogens. Putative agents can be classified by mechanism, as discussed previously, and include alkylating agents, topoisomerase II inhibitors, antimetabolite, and antitubulin drugs. The clinical syndrome is a late complication of these cytotoxic therapies, with a latency period between primary diagnosis and treatment-related disease ranging from months to years. While the morphologic abnormalities may vary (Godley and Larson, 2001; Jaffe, 2001; Thirman and Larson, 1996), there is a continuum in the percentage of marrow blasts from a MDS to overt AML (Larson and Le Beau, 2005).

Most *alkylating agents* used in cancer chemotherapy can cause MDS and/or AML, including cyclophosphamide, melphalan, busulfan, chlorambucil, and nitrosurea compounds such as carmustine, or BCNU (Casciato and Scott, 1979; Greene *et al.*, 1986). Other oncolytic agents implicated include azathioprine, procarbazine, doxorubicin, and bleomycin (Carver *et al.*, 1979; Valagussa *et al.*, 1979; Vismans *et al.*, 1980). The risk these drugs pose varies considerably with the therapeutic regimen. The incidence of MDS/AML in patients treated with alkylating agents has been reported to be 0.6% to 17%, with an average of 100-fold relative risk. Moreover, treatment-related MDS is associated with a substantially higher rate of transformation to AML than is primary or spontaneous MDS (Bitter *et al.*, 1987; Kantarjian *et al.*, 1986).

Treatment with *topoisomerase II inhibitors*, particularly the epipodophylotoxins etoposide and teniposide, can induce AML, the clinical course of which has the following distinguishing characteristics: (1) the absence of a preleukemic phase, (2) a short latency period, (3) frequent involvement of an M4/5 subtype, and (4) balanced chromosome aberrations involving chromosomes 11q23 and 21q22, among others (Larson and Le Beau, 2005; Murphy, 1993). Similar cytogenetic features have been observed following treatment with doxorubicin or dactinomycin (intercalating topoisomerase II inhibitors) in conjunction with alkylating agents and irradiation (Sandoval *et al.*, 1993).

Of the *aromatic hydrocarbons*, only benzene has been proven to be leukemogenic. While substituted aromatic hydrocarbons have long been suspected to be causative, due to the fact that preparations of xylene and toluene in the past contained as much as 20% benzene (Browning, 1965), clinical or experimental evidence for that is lacking (Irons, 1997).

Exposure to *high-dose γ - or x-ray radiation* has long been associated with ALL, AML, and CML, as demonstrated in survivors of the atom bombings of Nagasaki and Hiroshima (Cartwright *et al.*, 1964; Shimizu *et al.*, 1989). Less clear is the association of these diseases with low-dose radiation secondary to fallout or diagnostic radiographs (Cartwright *et al.*, 1964).

Other *controversial agents* include 1,3-butadiene, nonionizing radiation (electromagnetic, microwave, infrared, visible, and the high end of the ultraviolet spectrum), and cigarette smoking, for which published studies on the relationship to leukemia incidence is confusing, contradictory, or difficult to interpret based on dose response (Irons, 1997). Data suggesting that formaldehyde may be leukemogenic in humans have also been recently reviewed (Golden *et al.*, 2006). The results were similarly inconclusive.

TOXICOLOGY OF PLATELETS AND HEMOSTASIS

Hemostasis is a multicomponent system responsible for preventing the loss of blood from sites of vascular injury and maintaining circulating blood in a fluid state. Loss of blood is prevented by formation of stable hemostatic plugs mediated by the procoagulant

arm of hemostasis. This procoagulant response is normally limited to sites of vascular injury by the multicomponent regulatory arm of hemostasis. The dynamically modulated balance between procoagulant and regulatory pathways permits a rapid, localized response to injury. The major constituents of the hemostatic system include circulating platelets, a variety of plasma proteins, and vascular endothelial cells. The role of other cells in hemostasis, especially leukocytes, has been documented (Lane *et al.*, 2005; Monroe and Hoffman, 2005). Alterations in these components or systemic activation of this system can lead to the clinical manifestations of deranged hemostasis, including excessive bleeding and thrombosis. The hemostatic system is a frequent target of therapeutic intervention as well as inadvertent expression of the toxic effect of a variety of xenobiotics. This section briefly reviews the inadvertent effects of xenobiotics on hemostasis and the toxic effects of chemicals used to manipulate the hemostatic system.

Toxic Effects on Platelets

The Thrombocyte Platelets are essential for formation of a stable hemostatic plug in response to vascular injury. They initially adhere to the damaged wall through binding of von Willebrand factor (vWF) with the platelet glycoprotein Ib/IX/V (GP Ib/IX/V) receptor complex (Jurk and Kehrel, 2005). Ligand binding to GP Ib/IX/V or interaction of other platelet agonists (eg, thrombin, collagen, ADP, thromboxane A₂) with their specific receptors initiates biochemical response pathways that lead to shape change, platelet contraction, platelet secretion of granule contents, activation of the GP IIb/IIIa receptor, and externalization of phosphatidylserine (Jurk and Kehrel, 2005). Activation of the GP IIb/IIIa receptor permits fibrinogen and other multivalent adhesive molecules to form cross-links between nearby platelets, resulting in platelet aggregation. Xenobiotics may interfere with the platelet response by causing thrombocytopenia or interfering with platelet function; some agents are capable of affecting both platelet number and function.

Thrombocytopenia Like anemia, thrombocytopenia may be due to decreased production or increased destruction. Thrombocytopenia

is a common side effect of intensive chemotherapy, due to the predictable effect of antiproliferative agents on hematopoietic precursors, including those of the megakaryocytic lineage. It is a clinically significant component of idiosyncratic xenobiotic-induced aplastic anemia, as discussed previously. Indeed, the initial manifestation of aplastic anemia may be mucocutaneous bleeding secondary to thrombocytopenia.

Exposure to xenobiotics may cause increased immune-mediated platelet destruction through any one of several mechanisms (Table 11-9) (Aster, 2005; Aster and Bougie, 2007; Aster *et al.*, 2009; van den Bemt *et al.*, 2004). Some drugs function as haptens, binding to platelet membrane components and eliciting an immune response that is specific for the hapten. The responding antibody then binds to the hapten on the platelet surface, leading to removal of the antibody-coated platelet from the circulation. This type of antibody interaction can often be blocked *in vitro* by excess soluble drug that binds to the antibody and prevents its interaction with the platelet surface (van den Bemt *et al.*, 2004).

A second mechanism of immune thrombocytopenia is initiated by xenobiotic-induced exposure of a neoepitope on a platelet membrane glycoprotein. This elicits an antibody response, with the responding antibody binding to this altered platelet antigen in the presence of drug, resulting in removal of the platelet from the circulation by the mononuclear phagocytic system. The epitope specificity can be quite selective, as there is often little or no cross-reactivity between drugs having a very similar structure (eg, quinine and quinidine). This type of interaction is not inhibited *in vitro* by excess soluble drug, as the antibody target is a platelet-dependent epitope. Quinidine is a prototype of this type of mechanism and can induce antibodies directed at GP Ib/IX/V, GP IIb/IIIa, and/or platelet endothelial cell adhesion molecule-1 (PECAM-1) (van den Bemt *et al.*, 2004). Epitope heterogeneity has been described, regarding the binding site of these antibodies (Peterson *et al.*, 2008), which has been hypothesized to be due to the drug binding to and stabilizing denatured or nonnative conformations in these platelet receptors, which are then recognized as foreign and initiate a specific immune response (Li, 2010).

Table 11-9

Mechanism of Immune-Mediated Thrombocytopenia

MECHANISM	PROTOTYPIC AGENT	ANTIGEN/EPITOPE	PLATELET EFFECT	CLINICAL EFFECT
Hapten-directed antibody	Penicillin	Drug	Opsonization ↑ Clearance	Bleeding
Acquired antibody to drug-induced epitope	Quinidine	Drug–GP Ib/IX/V Drug–GP IIb/IIIa	Opsonization ↑ Clearance	Bleeding
Natural antibody to drug-induced epitope	Abciximab	GP IIb/IIIa	Opsonization ↑ Clearance	Bleeding
Induction of autoimmune antibodies	Gold	Platelet membrane	Opsonization ↑ Clearance	Bleeding
Immune complex	Heparin	PF 4–heparin complex	Platelet activation and aggregation ↑ Clearance	Thrombosis
Thrombotic thrombocytopenic purpura (TTP)	Ticlopidine	vWF-cleaving protease	Platelet activation Platelet aggregation ↑ Clearance	Microvascular thrombosis Microangiopathic hemolytic anemia
Hemolytic-uremic syndrome	Mitomycin	Unknown	Platelet activation and aggregation ↑ Clearance	Microvascular thrombosis Microangiopathic hemolytic anemia Renal failure

The diagnosis of drug-dependent antiplatelet antibodies can be quite difficult. Despite availability limited to specialized centers, flow cytometry is the most sensitive method for detecting drug-dependent antiplatelet antibodies. However, even this methodology has limitations, and must be interpreted with the clinical information. Therefore, these assays are not used in routine clinical practice. Consequently, the diagnosis is usually established by observing the resolution of thrombocytopenia following discontinuation of the offending drug. In most cases, the platelet count returns to normal within 5 to 10 days of drug discontinuation. Although a large number of chemicals have been implicated in the development of immune thrombocytopenia, the supporting evidence in many cases is weak (van den Bemt *et al.*, 2004).

A recent survey was conducted using three methods for identifying drugs that are associated with immune thrombocytopenia: published case reports; analysis of serum samples from affected patients for drug-dependent, platelet-reactive antibodies; and the Food and Drug Administration's Adverse Event Reporting System (Reese *et al.*, 2010). An astonishing 1444 drugs were found to have at least one report associated with thrombocytopenia, of which 573 demonstrated a statistically distinctive reporting association. Of 1468 drugs suspected as causal, 102 were evaluated by all three methods, of which 23 were found to have an association in all three.

Thrombocytopenia is an uncommon but serious complication of inhibitors of GP IIb/IIIa such as abciximab (Huxtable *et al.*, 2006). The mechanism appears to be related to exposure of epitopes on GP IIb/IIIa that react with naturally occurring antibodies. Because the reaction is dependent on antibodies formed prior to exposure to drug, it may occur shortly after the first exposure to the drug. Ligand binding is known to alter the conformation of GP IIb/IIIa. The GP IIb/IIIa inhibitors bind at the ligand binding site and also cause a conformational change in GP IIb/IIIa, permitting naturally occurring antibodies to bind to and initiate clearance of platelets by the mononuclear phagocytic system.

Heparin-induced thrombocytopenia (HIT) represents another mechanism of immune-mediated platelet destruction. This disorder is due to the development of antibodies that react with a multimeric complex formed by the interaction between heparin and a protein, usually platelet factor 4 (PF 4) (Davoren and Aster, 2006; Warkentin and Greinacher, 2004). When the relative concentration of heparin to PF 4 is appropriate, formation of this complex is associated with exposure of a neoepitope on PF 4 (or another target protein) and development of an IgG response to the neoepitope. The IgG then binds to the PF 4–heparin complex to form an immune complex that binds to the platelet Fc receptor, FcγRIIa. Clustering of platelet FcγRIIa by the immune complex activates biochemical signaling pathways mediated by the cytoplasmic domain of FcγRIIa. This results in platelet activation and aggregation. During the process of platelet activation, platelet microparticles that promote thrombin generation are released. Consequently, HIT is associated with both thrombocytopenia and an increased risk of arterial and venous thrombosis. Other drug–antibody complexes (eg, streptokinase–IgG) may trigger platelet activation and thrombocytopenia through a similar mechanism (Deckmyn *et al.*, 1998; McRedmond *et al.*, 2000).

TTP is a syndrome characterized by the sudden onset of thrombocytopenia, a microangiopathic hemolytic anemia, and multisystem organ failure, which often includes neurologic dysfunction. The syndrome tends to occur following an infectious disease but may also occur following administration of some drugs. The pathogenesis of TTP appears to be related to the ability of unusually large vWF multimers to activate platelets, even in the absence of significant vascular damage (Lian, 2005). Although these large multimers are normally secreted into blood by endothelial cells,

they are rapidly processed into smaller multimers by a protease (ADAMTS13) present in plasma. Acquired TTP is associated with the development of an antibody that inhibits this protease, permitting the very large vWF multimers to persist in the circulation (Lian, 2005; Veyradier and Meyer, 2005). Consequently, these multimers bind to platelet GP Ib/IX/V and induce platelet activation and aggregation. The organ failure and hemolysis in TTP is due to the formation of platelet-rich microthrombi throughout the circulation. The development of TTP or TTP-like syndromes has been associated with drugs such as ticlopidine, clopidogrel, cocaine, mitomycin, and cyclosporine (Veyradier and Meyer, 2005; Zakarija and Bennett, 2005). In some cases, drug-induced TTP is related to development of antibodies to ADAMTS13, whereas in other cases it may be due to direct endothelial cell toxicity from the drug.

The *HUS* is a disorder characterized by clinical features similar to those of TTP, with microangiopathic hemolytic anemia, thrombocytopenia, and renal failure (Zakarija and Bennett, 2005). Neurologic complications tend to be less severe, while renal failure often dominates the clinical picture. Sporadic cases of HUS have been linked to infection with verocytotoxin-producing *Escherichia coli*, but they may also occur during therapy with some drugs, including mitomycin. In contrast to TTP, the vWF-cleaving protease is normal in patients with HUS (Furlan *et al.*, 1998). The pathogenesis of the thrombocytopenia and microangiopathic changes in HUS is still uncertain, but there is experimental evidence suggesting that it is related to endothelial cell injury, with subsequent platelet activation and thrombus formation (Delvaeye *et al.*, 2009).

Desmopressin, a vasopressin analog, is an example of nonimmune-mediated increased platelet destruction. It induces a 2- to 5-fold increase in the plasma concentration of vWF and factor VIII. It is commonly used in the treatment of patients with von Willebrand disease and other mild bleeding syndromes. Desmopressin has been associated with the development or accentuation of thrombocytopenia in some patients with type 2B von Willebrand disease. The thrombocytopenia in such cases is related to the release of an abnormal vWF from endothelial cells. The abnormal vWF has enhanced affinity for GP Ib/IX/V and the interaction of the vWF with its receptor leads to platelet clearance from the circulation (Mannucci, 1998).

Toxic Effects on Platelet Function Platelet function is dependent on the coordinated interaction of a number of biochemical response pathways. A variety of drugs and foods have been found to inhibit platelet function, either *in vivo* or *in vitro* (Abrams, 2006). Major drug groups that affect platelet function include nonsteroidal anti-inflammatory drugs, β-lactam-containing antibiotics, cardiovascular drugs, particularly β-blockers, psychotropic drugs, anesthetics, antihistamines, and some chemotherapeutic agents. The effect of these drugs can vary between individuals, perhaps due to subclinical variations in underlying platelet function.

Xenobiotics may interfere with platelet function through a variety of mechanisms. Some drugs inhibit the phospholipase A₂/cyclooxygenase pathway and synthesis of thromboxane A₂ (eg, nonsteroidal anti-inflammatory agents). Other drugs appear to interfere with the interaction between platelet agonists and their receptors (eg, antibiotics, ticlopidine, clopidogrel). As the platelet response is dependent on a rapid increase in cytoplasmic calcium, any chemical that interferes with translocation of calcium may inhibit platelet function (eg, calcium channel blockers). Occasionally, drug-induced antibodies will bind to a critical platelet receptor and inhibit its function. The functional defect induced by such antibodies may potentiate the bleeding risk associated with the xenobiotic-induced thrombocytopenia. In some cases, the mechanism of inhibition is not known.

The effect of xenobiotics on platelet function can often be studied following *in vitro* exposure of platelets to the chemical of interest. However, evaluation following exposure is preferred, as metabolites of the parent compound may contain the platelet inhibitory activity. The most common method of assessing platelet function is turbidimetric platelet aggregation using platelet-rich plasma, but alternate techniques are available, including the PFA 100 analyzer, flow cytometry, and whole-blood impedance aggregometry (Cesar *et al.*, 2005; Matzdorff, 2005).

Toxic Effects on Fibrin Clot Formation

Coagulation Fibrin clot formation is the result of sequential activation of a series of serine proteases that culminates in the formation of thrombin (Lane *et al.*, 2005; Monroe and Hoffman, 2005). Thrombin is a multifunctional enzyme that converts fibrinogen to fibrin; activates factors V, VIII, XI, XIII, protein C, and platelets; and interacts with a variety of cells (eg, leukocytes and endothelial cells), activating cellular signaling pathways (Lane *et al.*, 2005).

The most common toxic effect of xenobiotics on fibrin clot formation are related to a decreased level of one or more of the critical proteins necessary for this process. The decrease in clotting factor activity may be due to decreased synthesis of the protein(s) or increased clearance from the circulation. Decreased synthesis is most often a reflection of hepatocellular damage or interference with vitamin K metabolism, as discussed below, whereas increased clearance is usually associated with the development of an antibody to a specific coagulation factor.

Decreased Synthesis of Coagulation Proteins The majority of proteins involved in the coagulation cascade are synthesized in the liver. Therefore, any chemical that impairs liver function may cause a decrease in production of coagulation factors. The common tests of the coagulation cascade, the prothrombin time (PT) and activated partial thromboplastin time (aPTT), may be used to screen for liver dysfunction and a decrease in clotting factors. These assays are often performed as part of the safety evaluation of a new chemical entity. The half-life of clotting factors in the circulation varies significantly, with factor VII having the shortest half-life (three–four hours). Therefore, with acute toxicity (eg, acetaminophen overdose), the effect on blood coagulation may be first seen as a decrease in the level of factor VII. Such a decrease would lead to prolongation of the PT with a normal aPTT. With a more chronic process, the PT, the aPTT, or both may be affected.

Factors II, VII, IX, and X are dependent on vitamin K for their complete synthesis (Stafford, 2005). Anything that interferes with vitamin K metabolism may lead to a deficiency of these factors and a bleeding tendency. This may occur with xenobiotics that interfere with absorption of vitamin K from the intestine or with chemicals that interfere with the reduction of vitamin K epoxide (Table 11-10). The

Table 11-10

Conditions Associated with Abnormal Synthesis of Vitamin K–Dependent Coagulation Factors

Warfarin and analogs	Intravenous α -tocopherol
Rodenticides (eg, brodifacoum)	Dietary deficiency Cholestyramine resin
Broad-spectrum antibiotics	Malabsorption syndromes
<i>N</i> -Methyl-thiotetrazole cephalosporins	

combination of antibiotic therapy and limited oral intake is a common cause of acquired deficiency of vitamin K–dependent proteins among hospitalized patients (Chakraverty *et al.*, 1996). The “super rodenticides” are another cause of acquired vitamin K deficiency (Berry *et al.*, 2000; Chua and Friedenber, 1998). These agents have a very prolonged half-life *in vivo*; thus, the coagulation defect may persist for weeks or months following exposure. Rodenticide exposure may occur accidentally, as part of a Munchausen syndrome, in association with a suicide attempt, or as part of a homicide attempt. At times it may be important to distinguish between a true vitamin K deficiency and interference with the reduction of vitamin K epoxide. This is most readily accomplished by measuring the level of vitamin K and vitamin K epoxide in serum or plasma. In the case of vitamin K deficiency, both vitamin K and vitamin K epoxide are decreased, whereas in the case of inhibition of vitamin K reduction, vitamin K epoxide is significantly increased. Specific rodenticides may be measured using HPLC techniques, but it is important to specify which active agent (eg, brodifacoum) should be measured, as the assays may not show cross-reactivity between agents.

Increased Clearance of Coagulation Factors Idiosyncratic reactions to xenobiotics include the formation of antibodies that react with coagulation proteins. These antibodies bind to the coagulation factor, forming an immune complex that is rapidly cleared from the circulation and resulting in deficiency of the factor. The antibody is often reversible over time if the initiating agent is withdrawn. However, during the acute phase, these patients may have life-threatening bleeding. The factors that are most often affected include factors VIII, V, and XIII, vWF, prothrombin, and thrombin (Table 11-11) (Lollar, 2004, 2005). Many of these antibodies

Table 11-11

Relationship between Xenobiotics and the Development of Specific Coagulation Factor Inhibitors

COAGULATION FACTOR	XENOBIOTIC
Thrombin	Topical bovine thrombin Fibrin glue
Factor V	Streptomycin Penicillin Gentamicin Cephalosporins Topical bovine thrombin
Factor VIII	Penicillin Ampicillin Chloramphenicol Phenytoin Methyldopa Nitrofurazone Phenylbutazone
Factor XIII	Isoniazid Procainamide Penicillin Phenytoin Practolol
von Willebrand factor	Ciprofloxacin Hydroxyethyl starch Valproic acid Griseofulvin Tetracycline Pesticides

inhibit the functional activity of the coagulation factor in addition to increasing the rate of clearance. Other antibodies have been demonstrated to have catalytic activity, resulting in proteolysis of the target coagulation factor (Ananyeva *et al.*, 2004).

Lupus anticoagulants are antibodies that interfere with *in vitro* phospholipid-dependent coagulation reactions (Bertolaccini *et al.*, 2004). Although it was once hypothesized that these antibodies were directed against phospholipid, it is now evident that lupus anticoagulants are directed against phospholipid-binding proteins, including prothrombin and β_2 -glycoprotein 1. These antibodies usually do not cause a deficiency of any specific coagulation factor. However, *in vivo*, these antibodies can potentiate procoagulant mechanisms and interfere with the protein C system. Consequently, these antibodies have been associated with an increased risk of thrombosis (Bertolaccini *et al.*, 2004). The development of lupus anticoagulants has been seen in association with a variety of medications, including procainamide, chlorpromazine, and hydralazine.

Toxicology of Chemicals Used to Modulate Hemostasis

Patients with bleeding or thrombotic problems are commonly encountered in clinical practice. A variety of agents are available to treat such patients, ranging from recombinant hemostatic proteins to chemical entities that modulate the activity of the coagulation system. The major toxicologic reactions to plasma-derived products are infectious diseases (eg, hepatitis C) and allergic reactions, which can be severe. The use of some products, such as activated concentrates of vitamin K–dependent proteins (eg, Autoplex and FEIBA), has been associated with the development of disseminated intravascular coagulation and/or thrombosis in some patients (Mannucci, 1998).

Oral Anticoagulants Oral anticoagulants (warfarin) interfere with vitamin K metabolism by preventing the reduction of vitamin K epoxide, resulting in a functional deficiency of reduced vitamin K (Ansell *et al.*, 2004). These drugs are widely used for prophylaxis and therapy of venous and arterial thrombosis. The therapeutic window for oral anticoagulants is relatively narrow, and there is considerable interindividual variation in the response to a given dose. A number of factors, including concurrent medications and genetics, affect the individual response to oral anticoagulants (Ansell *et al.*, 2004; D'Andrea *et al.*, 2005; Rojas *et al.*, 2005). For these reasons, therapy with these drugs must be routinely monitored to maximize both safety and efficacy. This is routinely performed with the PT, with results expressed in terms of the international normalized ratio (INR).

A number of xenobiotics, including foods, have been found to affect the response to oral anticoagulants (Ansell *et al.*, 2004). Perhaps the most common mechanism for interference with oral anticoagulants is mediated by inhibition of CYP2C9 (Rojas *et al.*, 2005). Other mechanisms of interference include induction of CYP2C9, which tends to diminish the effect of warfarin by shortening its half-life; interference with absorption of warfarin from the gastrointestinal tract; displacement of warfarin from albumin in plasma, which temporarily increases the bioavailability of warfarin until equilibrium is reestablished; diminished vitamin K availability, due to either dietary deficiency or interference with the absorption of this lipid-soluble vitamin; and inhibition of the reduction of vitamin K epoxide, which potentiates the effect of oral anticoagulants.

Just as other drugs interfere with the action of oral anticoagulants, administration of oral anticoagulants may affect the activity of other medications, particularly those that are metabolized by

CYP2C9. Dicumarol administration prolongs the half-life of chlorpropamide and phenytoin, resulting in hypoglycemia in the case of chlorpropamide and an increased plasma drug concentration in the case of phenytoin. Bis-hydroxycoumarin, but not warfarin, potentiates the activity of tolbutamide, resulting in enhanced hypoglycemia (Harder and Thurmann, 1996).

Oral anticoagulants have been associated with the development of warfarin-induced skin necrosis (Ansell *et al.*, 2004). This disorder is due to the development of extensive microvascular thrombosis in the affected skin. This uncommon toxic effect is thought to be related to a rapid drop in protein C following administration of the drug, resulting in impaired protein C function. The risk of developing warfarin-induced skin necrosis increases with the dose of warfarin used to initiate therapy, particularly when the initial dose exceeds 10 mg per day; this is one of the reasons that loading doses of warfarin are no longer recommended.

Vitamin K is necessary for the synthesis of proteins other than the coagulation-related factors, including osteocalcin, a major component of bone. Perhaps because of this, long-term administration of warfarin has been associated with bone demineralization (Ansell *et al.*, 2004; Stafford, 2005). This effect can be important in patients with borderline bone density. Administration of warfarin during pregnancy, particularly the first 12 weeks of pregnancy, is associated with congenital anomalies in 25% to 30% of exposed infants (Bates *et al.*, 2004). Many of the anomalies are related to abnormal bone formation. It is thought that warfarin may interfere with synthesis of proteins critical for normal structural development.

Heparin Heparin is a widely used anticoagulant for both prophylaxis and therapy of acute venous thromboembolism (Hirsh and Raschke, 2004). In many hospitals, the majority of patients are exposed to this potent anticoagulant at some point during their hospitalization. The major complication associated with heparin therapy is bleeding, a direct manifestation of its anticoagulant activity. The risk of bleeding is related to the intensity of therapy, the patient's body mass and underlying condition, and the presence of other hemostatic defects (eg, thrombocytopenia).

As discussed in the section "Toxic Effects on Platelets," heparin administration is also associated with the development of HIT. For unknown reasons, this complication occurs more frequently with heparin derived from bovine sources than with that derived from porcine sources. The incidence of HIT is also significantly higher in patients receiving unfractionated heparin than it is in patients receiving low-molecular-weight heparin (Davoren and Aster, 2006; Warkentin and Greinacher, 2004).

Long-term administration of heparin is associated with an increased risk of clinically significant osteoporosis (Dinwoodey and Ansell, 2006; Hirsh and Raschke, 2004). The mechanism underlying the development of osteoporosis in these patients is not known. Patients may suffer from spontaneous vertebral fractures and demineralization of long bones of the arms and legs. The risk of osteoporosis may be less with low-molecular-weight heparin as compared with that with unfractionated heparin.

Heparin administration may also cause a transient rise in serum transaminases, suggesting significant liver dysfunction (Guevara *et al.*, 1993). However, the rise is rapidly reversible on discontinuation of heparin and may reverse even before heparin is discontinued. The elevation of serum transaminases has not been associated with chronic liver dysfunction. The mechanism of heparin-induced increase in transaminases is not known.

In 2008, serious injuries and deaths were associated with the use of heparin originating in China. It was determined that certain sources of heparin were contaminated with oversulfated chondroitin sulfate (OSCS). The presence of OSCS is believed to be responsible

for the observed severe allergic reactions, gastrointestinal disturbances, and hypotension (Blossom *et al.*, 2008).

Fibrinolytic Drugs Fibrinolytic drugs are used in the treatment of acute thromboembolic disease with the goal of dissolving the pathogenic thrombus (Collen and Lijnen, 2005). Each of these drugs works by converting plasminogen, an inactive zymogen, to plasmin, an active proteolytic enzyme. Plasmin is normally tightly regulated and is not freely present in the circulation. However, administration of fibrinolytic drugs regularly results in the generation of free plasmin leading to systemic fibrin(ogen)olysis. The toxicology of the fibrinolytic drugs can be divided into toxic effects of systemic plasmin activation and toxic effects of the activators themselves.

Systemic fibrinolysis is associated with the development of a complex coagulopathy characterized by a decrease in fibrinogen, factors V and VIII, and α_2 -antiplasmin; an increase in circulating fibrin split products; degradation of platelet GP Ib/IX/V and IIb/IIIa; degradation of endothelial cell glycoproteins; degradation of fibronectin and thrombospondin; and prolongation of the PT, aPTT, and thrombin time (Hajjar, 2006). All of these effects potentiate the risk of bleeding. Anatomic locations that are frequently involved in bleeding complications include the cerebral circulation and sites of recent vascular access. As systemic plasmin can lyse physiologic as well as pathologic thrombi, reactivation of bleeding from sites of vascular access is not uncommon. Platelet inhibitors and heparin are commonly used in conjunction with fibrinolytic therapy to prevent recurrent thrombosis. As one might expect, the concurrent use of anticoagulants with systemic fibrinolysis may contribute to the risk of bleeding (Menon *et al.*, 2004).

Another complication associated with fibrinolysis is recurrent thrombosis at the site of pathologic thrombosis. While rethrombosis may be related to underlying damage to the vascular wall, there is some evidence that fibrinolytic therapy may contribute to this process. For example, plasmin, in appropriate concentrations, can actually induce platelet activation (McRedmond *et al.*, 2000). This process may be mediated by plasmin or streptokinase/plasminogen cleavage of the platelet thrombin receptor (protease activated receptor-1). Cleavage of the receptor is associated with activation of the platelet biochemical signaling pathways. There is sufficient “cross-talk” between the fibrinolytic system and the contact system of coagulation that one could also anticipate increased thrombin generation occurring as a result of fibrinolytic therapy (Schmaier *et al.*, 1999).

Streptokinase is a protein derived from group C β -hemolytic streptococci and is antigenic in humans. Antibody formation to streptokinase occurs commonly in association with streptococcal infections as well as exposure to streptokinase. Acute allergic reactions may occur in 1% to 5% of patients exposed to streptokinase, and these allergic reactions may consist of minor symptoms such as hives and fever as well as major, life-threatening anaphylactic reactions. In addition, delayed hypersensitivity reactions associated with severe morbidity may occur (Curzen *et al.*, 1998; Siebert *et al.*, 1992). Allergic reactions also occur with other fibrinolytic agents containing streptokinase (eg, anisoylated plasminogen–streptokinase complex) or streptokinase-derived peptides. The immune complex formed by IgG and streptokinase is capable of binding to and clustering platelet Fc γ RIIa, initiating platelet activation and aggregation (McRedmond *et al.*, 2000).

Urokinase and recombinant tissue plasminogen activator (t-PA) are generally not associated with allergic reactions. However, work is progressing on a number of genetically engineered forms of t-PA. Whether or not such mutant forms of t-PA

are immunogenic has not been firmly established (Collen and Lijnen, 2005).

Inhibitors of Fibrinolysis Inhibitors of fibrinolysis are commonly used to control bleeding in patients with congenital abnormalities of hemostasis, such as von Willebrand disease. Tranexamic acid and ϵ -aminocaproic acid are small molecules that block the binding of plasminogen and plasmin to fibrin and other substrate proteins through interaction with lysine binding sites on plasmin(ogen). Although relatively well tolerated, there is some evidence that administration of these chemicals may increase the risk of thrombosis due to the inhibition of the fibrinolytic system (Mannucci, 1998). In a single case, intravenous infusion of ϵ -aminocaproic acid in a patient with chronic renal failure was associated with acute hyperkalemia (Perazella and Biswas, 1999).

Aprotinin is a naturally occurring polypeptide inhibitor of serine proteases. It is usually derived from bovine material and consequently is immunogenic when administered to humans. Aprotinin is given by intravenous infusion, as it is inactive when given orally. Allergic reactions in response to aprotinin have been reported, ranging from minor cutaneous manifestations to anaphylactic reactions (Peters and Noble, 1999). A more recent observational study compared clinical outcomes after cardiac surgery performed with aprotinin, tranexamic acid, or ϵ -aminocaproic acid with outcomes after cardiac surgery without an inhibitor of fibrinolysis (Mangano *et al.*, 2006). In this study, use of antifibrinolytics was associated with decreased blood loss. However, use of aprotinin was associated with a significant increase in end-organ damage, including renal, cardiac, and cerebral events. The design and results of this study have been questioned, with calls for prospective randomized comparator studies (Sedrakyan *et al.*, 2006). The results also point out the intricate balance within the hemostatic system and the potential for problems when modulating the activity of one portion of this system.

RISK ASSESSMENT

Assessing the risk that exposure to new drugs, chemical products, and other agents poses to humans—in terms of significant toxic effects on hematopoiesis and the functional integrity of blood cells and hemostatic mechanisms—can be logistically and intellectually challenging. This is due in part to the complexity of hematopoiesis and the range of important tasks that these components perform, as previously discussed. A central issue in drug and nontherapeutic chemical development is the *predictive value* of preclinical toxicology data and the expansive but inevitably limited preregistration clinical database for the occurrence of significant hematotoxicity on broad exposure to human populations. Appropriately, this area of well-resourced applied toxicology is highly regulated yet provides unique and exciting opportunities for sophisticated, well-controlled research (Bloom, 1993).

Preclinical Risk Assessment

Most preclinical studies that assess the potential for candidate drugs or nontherapeutic chemicals to induce hematotoxicity in humans are performed in industry as part of the routine safety evaluation of these molecules. These studies are largely prescribed by government regulatory bodies of the various countries and regions, including the United States, the European Union, and Japan (ICH, 2000; Hall, 1992, 1997). The unique accessibility of blood as a potential target organ, which allows direct *ex vivo* assessment of the tissue (compared with the indirect parameters used to detect effects on

liver, kidney, etc), together with the use of hematologic monitoring to reflect systemic effects of other organ toxicity, enables more sensitive signal detection, and may account for the relatively high predictive value of these studies. In fact, earlier studies have shown that hematotoxicity that is preclinically identified predicts toxicity in human clinical trials with a 91% concordance (Olson *et al.*, 2000). It is doubtful, however, that preclinical animal studies are as predictive for today's candidate drug portfolios of highly targeted agents that include more human recombinant proteins, monoclonal antibodies, and targets that are specific to human tissue and disorders such as cancer and autoimmune disease. Another consequence is that more sophisticated biomarkers are increasingly required to demonstrate both pharmacodynamic and off-target effects in human and animal models, some of which provide opportunities for companion diagnostics and personalized medicine. Immunogenicity of heterologous proteins further complicates pharmacokinetic, pharmacodynamic, and safety assessment in animals. As a result, there is a greater sense of urgency to study these novel agents in humans. Accordingly, phase I clinical studies have become more important not only for safety assessment but also as a venue for early proof of concept experiments. Finally, as with other organ toxicity, the predictive value of preclinical studies for idiosyncratic iatrogenic disease in humans, such as aplastic anemia and agranulocytosis, is limited.

The issues relating to the assessment of blood as a target organ that confront the industrial toxicologist are largely similar to those of other target organs and include the selection of the appropriate animal model, how to best monitor for hematotoxicity, and the appreciation of species differences in responding to hematotoxic insults.

Animal Models and Hematologic Monitoring Selection of a species that is practical to study and predictive for hematotoxicity in humans is always a challenge. While this is driven in part by the aforementioned regulatory requirements, the selection is also influenced by other considerations, including having a pharmacokinetic profile comparable to that of humans, prior information on sensitivity of a particular species to a class of compounds, the ability to fully characterize effects on peripheral blood and bone marrow, and practical considerations, such as logistics and economics (Bloom, 1993). These become of particular importance in choosing a model to fully characterize the toxicity of a chemical known to have a hematotoxic potential.

Of the commonly used animal species, rats and mice offer the advantage of their small size, which favorably impacts test compound requirements and number of subjects that can be economically housed and tested. Both have been well characterized hematologically (Moore, 2000a,b; Valli and McGrath, 1997). Blood volume limitations, however, often prohibit the frequent, or serial, evaluation of blood and bone marrow required to characterize the progression of a hematotoxic effect. While this can be addressed in part through serial sacrifices, the inability to fully characterize individual animals poses a significant disadvantage. Test results will also vary in accordance with the phlebotomy site and method, particularly in rodents (Suber and Kodell, 1985), and with the physical and chemical restraint employed (Loomis *et al.*, 1980).

Serial blood and bone marrow sampling is practical in larger species, such as the dog and monkey. These models offer the additional advantage of being hematologically more similar to humans, as regards hematopoiesis and blood cell kinetics, which in the monkey extends to immunohematologic features (Ladiges *et al.*, 1990; Shifrine and Wilson, 1980). The latter species, however, presents more interanimal hematologic variability, particularly in

wild-caught primates, due to temperament, vascular access, and other influences, which include nutritional status and infection.

Tests used to assess blood and bone marrow in preclinical toxicology studies will vary with the phase or objective of the evaluation (acute, subacute, chronic), the intended use of the chemical, and what is understood or suspected regarding the toxicologic profile of the xenobiotic. Ideally, the studies in aggregate should provide information on the effects of single- and multiple-dose exposure on erythrocyte parameters (RBC, Hbg, PCV, MCV, MCHC), leukocyte parameters (WBC and absolute differential counts), thrombocyte counts, screening coagulation tests (PT, aPTT), peripheral blood cell morphology, and bone marrow cytologic and histologic features (Bloom, 1993; Lund, 2000; Weingand *et al.*, 1996). Notable are the applications of flow cytometry, which have been refined in recent years and recently reviewed regarding the advantages and disadvantages of these techniques in preclinical studies (Reagan *et al.*, 2011). Forward-angle scatter has been used to effectively type canine bone marrow hematopoietic cells (Weiss *et al.*, 2000), where that combined with side-angle scatter and the use of fluorochromes and lymphocyte-specific antibodies has been accurate and reproducible in rats (Chriswell *et al.*, 1998a). The latter correlates well with manual counts and has been used to characterize and quantitate the effects of phenylhydrazine, phlebotomy, cyclophosphamide, and various hematopoietic growth factors (Chriswell *et al.*, 1998b, 2000). Other techniques using cell surface markers have been used to enumerate subpopulations, which must be validated for each species due to variation in surface antigen expression and other preanalytical variables (Reagan *et al.*, 2011).

Additional tests should be employed in a problem-driven fashion, as required to better characterize findings from the aforementioned screening efforts or to more fully explore a class-specific effect or other hematotoxicologic potential of concern (Bloom, 1993). Examples of these tests are listed in Table 11-12. While much progress has been made in validating many of the more specialized assays in our principal animal models, additional validation that addresses laboratory- and species-specific preanalytical and analytical variables is often required.

Table 11-12

Examples of Problem-Driven Tests Used to Characterize Hematologic Observations in Preclinical Toxicology

Flow cytometry (see text)
Heinz body preparation
Cell-associated antibody assays (erythrocyte, platelet, neutrophil)
Erythrocyte osmotic fragility test
Erythrokinetic/ferrokinetic analyses
Cytochemical/histochemical staining
Electron microscopy
In vitro hematopoietic clonogenic assays
Platelet aggregation
Plasma fibrinogen concentration
Clotting factor assays
Thrombin time
Bleeding time

Despite the importance of bone marrow assessment in detecting and characterizing hematotoxicity, there is remarkably little regulatory guidance on indications, frequency, or preferred techniques. The Federal Drug Administration (FDA) Centers for Drug (CDER) and Biologic (CBER) Evaluation and Research, and the European Medicines Agency (EMA) have issued guidelines largely in the context of immunotoxicity risk assessment (Food and Drug Administration *et al.*, 2006; European Medicines Agency and Committee for Proprietary Medicinal Products, 2006). Limited guidance is also provided by Japan's Ministry of Health, Labor and Welfare, the FDA's Center for Veterinary Medicine, and the Environmental Protection Agency (Reagan *et al.*, 2011). To address this gap, a joint effort of the American Society for Veterinary Clinical Pathology and the Society of Toxicologic Pathology (Bone Marrow Working Group) has resulted in a recent publication on best practices for evaluation of bone marrow in nonclinical toxicity studies (Reagan *et al.*, 2011).

Because hematologic features and response to disease can vary substantially among animal species, it is essential that the toxicologist fully understands the hematology of the animal model used for preclinical risk assessment. While complete and accurate reference data are helpful, they do not provide information on pathophysiology that may be species-specific and required to accurately interpret the preclinical data. Examples of these features include the relative influence of preanalytical variables (blood collection technique, nutritional status, sample stability), response to blood loss or hemolysis, stress effects on the leukogram, susceptibility to secondary effects associated with other target organ toxicity, etc. It is beyond the scope of this chapter to fully discuss the comparative hematology of laboratory animals, which is provided in several excellent reviews (Feldman *et al.*, 2006; Valli and McGrath, 1997).

In Vitro Bone Marrow Assays As with other target organ risk assessment, in vitro methods for assessing potential hematotoxicity are attractive in that they are faster and less expensive than in vivo studies, while providing data that often suggest or clarify the mechanism of a toxic effect. Drug- or chemical-induced bone marrow suppression can result from effects on specific hematopoietic stem cells or on the hematopoietic microenvironment. These effects can be distinguished and confirmed using short-term clonogenic assays and long-term functional assays, respectively (Deldar, 1994; Naughton *et al.*, 1992; Williams *et al.*, 1988). The former include burst-forming-unit erythroid (BFU-E), colony-forming-unit erythroid (CFU-E), colony-forming-unit granulocyte/monocyte (CFU-GM), colony-forming-unit megakaryocyte (CFU-MK), and colony-forming-unit granulocyte, erythroid, megakaryocyte, monocyte (CFU-GEMM), which have been developed for several laboratory animal species (Deldar and Parchment, 1997; Pessina *et al.*, 2005). It is therefore possible to examine effects on the myeloid, erythroid, and megakaryocytic lineages in a fashion where concentrations of the chemical are tightly controlled, as is duration of exposure to it.

While the most commonly applied clonogenic techniques used to assess the above still employ viscous or semisolid matrices and culture supplements that promote differentiation of the hematopoietic cells (Erickson-Miller *et al.*, 1997; McMullin *et al.*, 1998), some newer techniques measure intracellular ATP, which is influenced by artifacts such as apoptosis, cytotoxicity, necrosis, and fibroblast contamination (Fan and Wood, 2007; Slater, 2001). Several commercial services are available that provide stem cells of human, canine, primate, and rodent origin to which are added cytokines and growth factors to support cell development (Reagan *et al.*, 2011).

In vitro clonogenic assays are best used in a preclinical setting in combination with in vivo testing. Used in this way, the predictive value of these assays is enhanced. This has been particularly true for anticancer and antiviral drugs, where the in vitro component of risk assessment has been used for therapeutic index-based screening to identify less myelosuppressive analogs, structure-toxicity relationships, and new-drug lead candidates (Deldar and Stevens, 1993; Parchment *et al.*, 1993; Pessina *et al.*, 2003). Other advantages of the in vitro hematopoietic stem cell assays include the opportunities they provide to test combinations of chemicals as well as their metabolites and effects of serum and other cell components, such as lymphocytes (Deldar and Parchment, 1997). Most important is the ability to test human hematopoietic cells directly in a preclinical setting, thus obviating extrapolation considerations. Concern for possible metabolic activation can be addressed by culturing the target cells in question with metabolizing systems in a cell-free extract (s9), with isolated hepatocytes, or with other CYP450-expressing cell types (Frazier, 1992; Negro *et al.*, 2001).

Perhaps the most interesting use of these in vitro clonogenic assays in risk assessment has been their role in making practical interspecies comparisons regarding sensitivity to a particular agent or group of drugs or chemicals. Comparisons to the sensitivity of human cells can be made that have implications for the relative predictive value of various animal models for hematotoxicity in humans. Examples include the resistance of murine CFU-GM to the anticancer drug topotecan relative to that of the canine and human cells (Deldar and Stevens, 1993). This is consistent with the early observations of Marsh—that the dog is a particularly predictive model for the myelosuppression associated with anticancer drugs in humans (Marsh, 1985). Thus, while some chemicals show comparable suppressive activity across species lines (doxorubicin, pyrazoloacridine, hepsulfan, cyclopentenyl cytosine), others, such as camptothecins, carboxyamidotriazole, and fostriecin, show differences of as much as three log concentrations (Du *et al.*, 1991; Horikoshi and Murphy, 1982; Reagan *et al.*, 1993).

Because myelotoxicity, and particularly suppression of granulopoiesis, is a major limitation in administering anticancer drugs, and is often used to determine the optimal dose, the clonogenic assay for CFU-GM has received the most attention as a preclinical tool for predicting this response. It is the only assay that has been validated by an international study supported by the European Centre for Validation of Alternative Methods (ECVAM) (Pessina *et al.*, 2003). Analytical validation was completed for the human and mouse assays, and a predictive model was developed to calculate the maximum tolerated dose (MTD) in humans using data from the mouse assay that is adjusted for the established interspecies variation (Pessina *et al.*, 2001). The model was applied in an international blind trial to 20 drugs that included 14 antineoplastic drugs, the antiviral drugs zidovudine and acyclovir, and the pesticide lindane (Pessina *et al.*, 2003). It predicted the MTD for all 20 chemicals, although extrapolation on the regression curve out of the range of the actual drug doses tested was required to derive the IC90 for 10 of these drugs. Since then, the Scientific Advisory Committee of the ECVAM endorsed the CFU-GM assay for predicting acute neutropenia in humans as a substitute to using a second species, such as the dog, for this purpose (24th meeting at ECVAM of the ECVAM Scientific Advisory Committee, European Commission, March 2006). Subsequent studies have confirmed the predictive value of this assay in both anticancer drugs (Masubuchi, 2006) and nononcology candidate drugs (Horn *et al.*, 2008). The latter study illustrates the species specificity encountered and the importance of integrating the in vivo and in vitro approaches

required to fully characterize the hematotoxicity observed in pre-clinical safety assessment today.

While this discussion has focused on *in vitro* hematopoietic clonogenic assays in the context of risk assessment, these assays have also proven to be extraordinarily useful tools for investigating mechanisms of toxic cytopenia in humans (Deldar, 1994). Parchment and Murphy (1997) review the application of these to four categories of hematologic toxicity observed clinically: (1) the reversible cytopenia following acute exposure to a cytotoxic or cytostatic chemical; (2) the permanent loss in the production of a mature blood cell type(s); (3) cytosis, or the dramatic increase in blood cell counts following single or repeated toxicant exposure; and (4) the progressive loss of one or more blood cell lineages during chronic exposure to a toxicant. In all these circumstances, *in vitro* and *ex vivo* hematopoietic clonogenic assays have proven useful in understanding the mechanism(s) of these toxic effects and formulating strategies for risk management and treatment.

Emerging Technologies As discussed previously, the well-controlled and resource-intensive preclinical toxicology and safety studies prescribed for candidate drugs and nontherapeutic chemicals provide unique opportunities for studies on mechanisms of xenobiotic-induced hematotoxicity (Bloom, 1993; Deldar and Parchment, 1997). Together with the traditional biomarkers for toxicity, mechanism-based technologies such as toxicogenomics, proteomics, and metabonomics are now available to the toxicologist and are increasingly helpful in both predicting toxicity and determining whether a particular finding is relevant to humans (Todd and Ulrich, 1999). Challenges that the application of these tools presents relate to informatics, standardization, and validation (Reynolds, 2005).

Clinical Trials and Risk Assessment

As with preclinical risk assessment, most of the clinical research on hematotoxicity is driven by regulatory requirements and supported by the drug, cosmetic, and chemical industries. The challenges and opportunities this presents are similar to those in preclinical development with the following differences. Most clinical studies involve actual patients with the targeted disease, in contrast to the inbred, healthy, well-defined animals employed in preclinical studies. This presents additional variables and challenges to manage. Second, the scale of clinical trials, the volume of data produced, and the resources required exceed by orders of magnitude those of preclinical studies. Third, many clinical trials involve research cooperative groups that represent a network of clinical scientists from academic medical centers, such as the Eastern Cooperative Oncology Group (ECOG), the AIDS Clinical Trial Group (ACTG), Thrombolysis in Myocardial Infarction (TIMI), and others. Most of the information on drug- or chemical-induced hematotoxicity in humans is collected through this industry-sponsored and highly regulated clinical research.

It is well understood that the ways in which drugs and nontherapeutic chemicals affect the hematopoietic system are influenced by both the nature of the chemical and the response of the subject or target population. As discussed previously, many chemicals are known to induce dose-dependent hematotoxicity in a fashion that is highly predictable. Others cause toxicity in a small number of susceptible individuals, and these often include chemicals not otherwise hematotoxic in most individuals (Dieckhaus *et al.*, 2002; Patton and Duffull, 1994). These *idiosyncratic reactions* present the biggest challenge as regards detection and characterization before human patients or populations are broadly exposed. They include aplastic anemia, thrombocytopenia, hemolysis, and

leukopenia, which may or may not be immune-mediated (Salama *et al.*, 1989).

Prevailing theories today, as regards mechanisms for these idiosyncratic reactions, have been discussed previously. The chemical structure can be a risk factor if it is similar to that of other known toxicants. Patient- or population-related risk factors include pharmacogenetic variations in drug metabolism and detoxification that lead to reduced clearance of the chemical or production of novel intermediate metabolites (Cunningham *et al.*, 1974; Gerson *et al.*, 1983; Mason and Fischer, 1992), histocompatibility antigens (Frickhofen *et al.*, 1990), interaction with drugs or other chemicals (West *et al.*, 1988), increased sensitivity of hematopoietic precursors to damage (Vincent, 1986), preexisting disease of the bone marrow, and metabolic defects that predispose to oxidative or other stresses associated with the chemical (Stern, 1989).

In drug development, the clinical evaluation of candidate molecules is usually performed in 3 phases: *Phase I* examines the effect of single and multiple increasing doses in small numbers of normal and/or patient volunteers. Pharmacokinetic properties are usually addressed, as well as the routes of excretion and metabolism; and the assessment of active and inactive metabolites. The emphasis is usually on safety assessment. *Phase II* includes controlled studies in the target patient population that examine both safety and efficacy. They explore dose response and usually provide the first indication of benefit versus risk. *Phase III* entails larger studies designed to confirm efficacy in an expanded patient population and evaluate less frequent adverse effects, such as the aforementioned idiosyncratic blood dyscrasias.

Development of a demonstrably hematotoxic drug is usually stopped in phase I or II, unless the indication includes life-threatening conditions where toxicity is acceptable (eg, anticancer drugs). Thus, drugs tested in phase III generally show an acceptable safety profile in most subjects at the doses used. Even phase III studies, however, are not usually powered to detect the low incidence of idiosyncratic hematotoxicity previously discussed (Levine and Szarfman, 1996). In order to detect one adverse event affecting 1% of an exposed patient population at a 95% confidence level, a trial must include approximately 300 subjects (O'Neill, 1988). Clinical databases supporting new drug applications generally cannot be used to detect adverse events that occur below 1 per 1000 exposures (ICH, 2001), and most will not rule out events with a frequency of less than 1 per 500 (Szarfman *et al.*, 1997). Thus, rare, delayed, or cumulative toxicity is often missed in preregistration clinical trials.

Detection of low-incidence hematotoxicity is usually achieved through postmarketing surveillance, such as the MedWatch program introduced by the FDA in 1993 (Szarfman *et al.*, 1997). Other countries that practice comprehensive postmarketing surveillance include Canada, the United Kingdom, Sweden, Germany, France, Australia, and New Zealand. Adverse event data, including serious hematotoxicity, are provided to the WHO; this information is compiled by a computer-based recording system employing WHO terminology and system and organ classifications for adverse reactions (Edwards *et al.*, 1990). Examples of iatrogenic blood dyscrasias detected through postmarketing surveillance include the hemolysis and thrombocytopenia associated with the antibiotic temafloxacin, the aplastic anemia linked to the antiepileptic felbamate, the hemolysis caused by the antidepressant nomifensine, and the agranulocytosis associated with the antiarrhythmic aprindine.

The WHO has also established criteria for grading hematotoxicity (WHO, 1979), which are summarized in Table 11-13. These have been particularly useful in establishing and communicating treatment strategies and guidelines for chemicals known to suppress hematopoiesis (cytoreductive oncolytic, immunosuppressive, and

Table 11-13

WHO Grading Criteria for Subacute and Acute Hematotoxicity

HEMATOLOGIC PARAMETERS (ADULTS)	GRADE 0	GRADE 1	GRADE 2	GRADE 3	GRADE 4
Hemoglobin (g/dL) (nmol/L)	11.0 (6.8)	9.5–10.5 (6.5–6.7)	8.0–9.4 (4.95–5.8)	6.5–7.9 (4.0–4.9)	6.5 (4.0)
Leukocytes (1000/ μ L)	4.0	3.0–3.9	2.0–2.9	2.0–1.9	1.0
Granulocytes (1000/ μ L)	2.0	1.5–1.9	1.0–1.4	0.5–0.9	0.5
Platelets (1000/ μ L)	100	75–99	50–74	25–49	<25
Hemorrhage, blood loss	None	Petechiae	Mild	Gross	Debilitating

antiviral agents, etc) and for which this limiting toxicity is used to establish MTDs for individual patients.

Greater risk is acceptable with these drugs due to the life-threatening conditions they are used to treat. Similar risk–benefit decisions are also made regarding the use of drugs that cause blood dyscrasias in an idiosyncratic fashion, as previously discussed. Some are used to treat nonmalignant or life-threatening conditions, the risk of which is managed through rigorous laboratory monitoring. Examples include felbamate, ticlopidine, and clozapine, as discussed previously. Postmarketing surveillance plays a critical role in measuring the effectiveness of such monitoring.

Critical to the effectiveness of such surveillance by manufacturers and government regulatory agencies is the ability to detect a “signal,” such as that related to life-threatening idiosyncratic hematotoxicity. Over the past five years, regulatory agencies and drug monitoring centers have been developing computerized data mining methods to better identify reporting relationships in spontaneous reporting databases that have enabled and optimized such signal detection (Almenoff *et al.*, 2005). This includes the use of screening algorithms and computer systems that efficiently signal higher-than-expected combinations of drugs and events in the FDA’s spontaneous reports database, such as aplastic anemia, agranulocytosis, and idiopathic thrombocytopenic purpura. Examples include the Multi-Item Gamma Poisson Shrinker (MGPS) program, which computes signal scores for pairs, and for higher-order (eg, triplet, quadruplet) combinations of xenobiotics and events that are significantly more frequent than their pairwise associations would predict (Szarfman *et al.*, 2002). Such tools provide an objective and unprecedented systematic and simultaneous view of these large databases and alert government and manufacturers to critically important new safety signals that inform the toxicologist.

New Frontiers and Challenges in Immunotoxicology

INTRODUCTION

Immunotoxicology can be most simply defined as the study of adverse effects on the immune system resulting from occupational, inadvertent, or therapeutic exposure to drugs, environmental chemicals, and, in some instances, biological materials. Studies in animals and humans have indicated that the immune system is comprised of potential target organs, and that damage to

this system can be associated with morbidity and even mortality. Indeed, in some instances, the immune system can be compromised (decreased lymphoid cellularity, alterations in lymphocyte subpopulations, decreased host resistance, and altered specific immune function responses) in the absence of observed toxicity in other organ systems. These studies coupled with tremendous advances made in immunology and molecular biology have led to a steady and exponential growth in our understanding of

immunotoxicology during the past 30 years. Recognition by regulatory agencies that the immune system is an important, as well as sensitive, target organ for chemical- and drug-induced toxicity is another indication of the growth of this subdiscipline of toxicology. With the availability of sensitive, reproducible, and predictive tests, it is now apparent that the inclusion of immunotoxicity testing represents a significant adjunct to routine safety evaluations for therapeutic agents, biological agents, and chemicals now in development.

Understanding the impact of toxic responses on the immune system requires an appreciation of its role, which may be stated succinctly as the preservation of integrity. It is a series of delicately balanced, complex, multicellular, and physiological mechanisms that allow an individual to distinguish foreign material (ie, “nonself”) from “self,” and to neutralize, eliminate, and/or coexist with the foreign matter. Examples of self are all the tissues, organs, and cells of the body. Examples of nonself are a variety of opportunistic pathogens, including bacteria and viruses, and transformed cells or tissues (ie, tumors). The immune system is characterized by a virtually infinite repertoire of specificities, highly specialized effectors, complex regulatory mechanisms, and an ability to travel throughout the body. The great complexity of the mammalian immune system is an indication of the importance, as well as the difficulty, of its role. If the immune system fails to recognize as nonself an infectious entity or neoantigens expressed by a newly arisen tumor, then the host is in danger of rapidly succumbing to the unopposed invasion. This aspect of immune competence is the reason why the immune system is often synonymous with “host defense.” Alternatively, if some integral bodily tissue is not identified as self, then the immune system is capable of turning its considerable defensive capabilities against that tissue, and an autoimmune disease may be the end result. This aspect of immunocompetence emphasizes the tremendous destructive potential that is associated with the host defense mechanisms of the immune system. The cost to the host of these mistakes, made in either direction, may be quite high. The fact that mistakes can occur in either direction is an indication that immunotoxicology should be considered as a continuum (Fig. 12-1). At the center of the concept of the continuum is the recognition that immune responses in the normal human population can vary by more than two standard deviations (Luebke *et al.*, 2004), as described in greater detail in the subsection entitled “Approaches to the Assessment of Human Immunotoxicity.” Because the cost of mistakes in immunocompetence can be so high, and because of

Figure 12-1. The continuum of immunotoxicology. Immune toxicity results from xenobiotic-induced suppression or enhancement of immune function.

the tremendous diversity involved in the identification of self versus nonself, a complex array of organs, cells, soluble factors, and their interactions has evolved to regulate this system and minimize the frequency of errors in either direction. Due to the potentially profound effects resulting from disruption of the delicately balanced immune system, there is a need to understand the cellular, biochemical, and molecular mechanisms of xenobiotic-induced immune modulation.

This chapter provides (1) an overview of basic concepts in immunology (structure, components, and functions), which are important to the understanding of the impact that xenobiotics may have on the exposed individual; (2) a summary of selected current methods utilized to assess immune function; and (3) a brief review of current information on the immune modulation (immune suppression, immune enhancement, hypersensitivity, and autoimmunity) induced by a variety of xenobiotics. This chapter is not meant to be an immunology textbook, nor an exhaustive review of the mechanisms of immunotoxicity of a myriad of xenobiotics. For detailed information on immunology, the reader is referred to three texts: the first edited by Paul, *Fundamental Immunology* (6th edition, 2008), the second written by Delves, Martin, Burton, and Roitt, *Roitt's Essential Immunology* (12th edition, 2011), and the third written by Murphy, Travers, and Walport, *Janeway's Immunobiology* (7th edition, 2008). For a more comprehensive review of immunotoxicology, the reader is referred to two texts: the first edited by Vohr and colleagues, *Encyclopedic Reference of Immunotoxicology* (2005), and the second edited by Luebke, House, and Kimber, *Immunotoxicology and Immunopharmacology, Target Organ Toxicity Series* (3rd edition, 2007). The reader might also find the list of abbreviations in Table 12-1 helpful.

THE IMMUNE SYSTEM

Unlike most organ systems, the immune system has the unique quality of not being confined to a single site within the body. It comprises numerous lymphoid organs (Table 12-2) and many different cellular populations with a variety of functions. The bone marrow and thymus are referred to as primary lymphoid organs because they contain the microenvironments capable of supporting the production of mature B and T cells, respectively. Central tolerance (nonreactive to self-antigens) is also established in the primary lymphoid organs to prevent the maturation of lymphocytes that recognize self-antigens. In addition, the bone marrow is the site of origin of the pluripotent and self-renewing hematopoietic stem cell (HSC) from which all other hematopoietic cells are derived. While immunologists differ on how to define and identify the hematopoietic intermediates, Fig. 12-2 shows one model of hematopoiesis (adapted from Baltimore *et al.* 2008; Chaplin, 2010). During gestation, the HSC is found in the embryonic yolk sac and fetal liver; eventually, it migrates to the bone marrow. Within the bone marrow, the HSC developmentally commits to either the lymphoid or myeloid lineages by giving rise to the common lymphoid progenitor (CLP) or the common myeloid progenitor (CMP), which differentiate into various types of hematopoietic cells. CLP cells make a further commitment to become either T cells or B cells (Fig. 12-3). The maturation process for both T cells and B cells involves the establishment of central tolerance, but this process occurs at different primary lymphoid organs. For B cells, central tolerance occurs in the bone marrow and simply involves the removal of self-reactive cells. It is more complex for T cells and involves the migration of T-cell precursors from the bone marrow to the thymus where they undergo a process of both positive and negative selection resulting in mature T cells that recognize the host's cells

Table 12-1

Abbreviations

TERM	ABBREVIATION	TERM	ABBREVIATION
Antibody-dependent cell-mediated cytotoxicity	ADCC	Interleukin	IL
Antibody-forming cell	AFC	Keyhole limpet hemocyanin	KLH
Antigen-presenting cell	APC	Lipopolysaccharide	LPS
Aryl hydrocarbon receptor	AHR	Local lymph node assay	LLNA
B-cell receptor	BCR	Major histocompatibility complex	MHC
B-regulatory cell	Breg	Membrane attack complex	MAC
Carboxyfluorescein succinimidyl ester	CFSE	Mixed lymphocyte response	MLR
CD40 ligand	CD40L	National Toxicology Program	NTP
Cell-mediated immunity	CMI	Natural killer	NK
Central nervous system	CNS	NOD-like receptors	NRL
Cluster of differentiation	CD	Non-human primates	NHP
Colony stimulating factor	CSF	Pathogen-associated molecular patterns	PAMPs
Common lymphoid progenitor	CLP	Pattern recognition receptors	PRR
Common myeloid progenitor	CMP	Peripheral blood mononuclear cells	PBMC
Concanavalin-A	Con A	Phytohemagglutinin	PHA
Conventional dendritic cell	cDC	Plaque-forming cell	PFC
Cytotoxic T lymphocyte	CTL	Plasmacytoid dendritic cell	pDC
Danger-associated molecular patterns	DAMPs	Polymerase chain reaction	PCR
Delayed-type hypersensitivity	DTH	Pre/postnatal development	PPND
Dendritic cell	DC	RIG-like receptors	RLR
Developmental and reproductive toxicology	DART	Reverse transcriptase	RT
Developmental immunotoxicology	DIT	Sheep red blood cells	sRBC
Embryo fetal development	EFD	Single nucleotide polymorphism	SNP
Experimental allergic encephalomyelitis	EAE	Systemic lupus erythematosus	SLE
Hematopoietic stem cell	HSC	T-cell receptor	TCR
Human lymphocyte activation	HuLa	T cytotoxic cell	Tc
Human peripheral blood	HPB	T helper cell	Th
Interferon	IFN	Toll-like receptor	TLR
Immunoglobulin	Ig	T-regulatory cell	Treg
Innate lymphoid cell	iLC	Transforming growth factor	TGF
		Tumor necrosis factor	TNF

(ie, positive selection) but not too strongly. T cells that recognize self too strongly are deleted from the T-cell repertoire (ie, negative selection). Recognition of self is essential for T cells to initiate and regulate immune responses.

Table 12-2

Organization of the Immune System: Lymphoid Tissue

CLASSIFICATION	LYMPHOID ORGANS
Primary	Bone marrow Thymus
Secondary	Spleen Lymph nodes Peyer's patches Skin-associated lymphoid tissue (SALT) Mucosal lamina propria (MALT) Gut-associated lymphoid tissue (GALT) Bronchial-associated lymphoid tissue (BALT) Nasal-associated lymphoid tissue (NALT) Cells lining the genitourinary tract
Tertiary	Lymphoid neogenesis in nonlymphoid organs

Figure 12-2. Development of the cellular components of the immune system. All immune cells initially develop in the bone marrow. The HSC differentiates into two main progenitors from which all other cells develop. The progenitor for pDCs is still unclear (dashed lines). HSC, hematopoietic stem cell; CMP, common myeloid progenitor; CLP, common lymphoid progenitor; GMP, granulocyte-macrophage progenitor; MEP, megakaryocyte-erythrocyte progenitor; DC, dendritic cell; pDC, plasmacytoid dendritic cell; EP, erythrocyte precursor; NK, natural killer; RBC, red blood cells.

Figure 12-3. Development and differentiation of T and B cells. T cells develop in the thymus and B cells develop in the bone marrow. For T cells, an initial step is commitment to either $\alpha\beta$ or $\gamma\delta$ TCR. After positive and negative selection, T cells acquire either CD4 or CD8 to become Th or Tc, respectively, become natural Tregs (nTregs), or become NKT cells. The B-cell lineage depicted here is of the conventional B-2 lineage. B-1 cells are not depicted since these cells arise from a distinct precursor not found in the bone marrow, which might be a precursor that can generate B-1 or myeloid cells. m, membrane.

Mature, naive, or virgin lymphocytes (those T and B cells that have never undergone antigenic stimulation) are first brought into contact with exogenously derived antigens within the highly organized microenvironment of the spleen and lymph nodes, which are secondary lymphoid organs. These organs can be thought of as biological sieves. The spleen serves as a filter for the blood, removing both foreign antigens and any circulating dead cells and cellular debris. The lymph nodes are part of a network of lymphatic veins that filter antigens from the fluid surrounding the tissues of the body. In addition to the spleen and lymph nodes, other secondary lymphoid tissues associated with the skin, mucosal lamina propria, gut, bronchioles, or nasal cavity are referred to as associated lymphoid tissues (abbreviated SALT, MALT, GALT, BALT, and NALT, respectively). Included in the GALT are specialized structures in the small intestine called Peyer's patches that collect antigens from the gastrointestinal tract. The associated lymphoid tissues tend to have more exposure to antigen and greater plasticity (ie, increase or decrease in size and/or number) than lymph nodes. The plasticity of lymphoid organs is underscored by the detection of lymphoid neogenesis in nonlymphoid organs during chronic inflammation. The new lymphoid tissue is classified as tertiary lymphoid tissue, and its development is reversible if the inflammatory response is resolved. Although studies suggest that tertiary lymphoid tissues support transient, local immune responses, there is still much to learn regarding lymphoid neogenesis and its role in the immune response particularly with clinical and experimental evidence supporting an association between lymphoid neogenesis (ie, tertiary lymphoid tissues) and pathophysiological conditions such as autoimmune disease and cancer (Drayton *et al.*, 2006).

Antigen Recognition

Immunity Mammalian immunity can be classified into two functional divisions: innate immunity and acquired (adaptive) immunity (Table 12-3). Innate immunity has historically been characterized as a first-line defense response with little immunological memory.

Table 12-3

Innate versus Acquired Immunity

CHARACTERISTIC	INNATE IMMUNITY	ACQUIRED IMMUNITY
Cells involved	Neutrophils Macrophages NK/NKT cells DC	T cells B cells Macrophages (accessory cell) DC (accessory cell)
Primary soluble mediators	Complement Perforin/granzyme Acute-phase proteins IFN- α/β Other cytokines	Antibody Cytokines Perforin/granzyme
Specificity of response	Limited	Yes (very high specificity)
Receptors	TLR Complement receptors NLR Fc TCR $\gamma\delta$	TCR $\alpha\beta$ TCR $\gamma\delta$ Ig $\alpha\beta$
Response enhanced by repeated antigen challenge	No	Yes

Therefore, in a normal healthy adult, the magnitude of the innate immune response to a foreign organism is similar for a secondary or a tertiary challenge as it is for the primary exposure. By contrast, acquired (adaptive) immunity is characterized by specificity and immunological memory. Thus, in a normal healthy adult, the speed and magnitude of the acquired immune response to a foreign organism is greater for a secondary challenge than it is for the primary challenge.

Antigen The primary determinant in either type of immune response is the ability of the immune system components to recognize self versus nonself. One definition of nonself, essentially, is anything other than that encoded in one's own germline genome (Nathan, 2006). Given this broad interpretation of nonself, this includes foreign DNA, RNA, protein, and carbohydrates, and may even include aberrantly expressed or mutated self-proteins, since those are likely not contained in one's own germline genome. A nonself substance that can be recognized by the immune system is called an antigen (also referred to as an immunogen or allergen). Antigens are usually (but not absolutely) biological molecules that can be cleaved and rearranged for presentation to other immune cells. Generally, antigens are about 10 kDa or larger in size. Smaller antigens are termed "haptens" and must be conjugated with carrier molecules (larger antigens) in order to elicit a specific response. However, once an initial response is made, the hapten can induce subsequent responses in the absence of the carrier.

Antibodies Antibodies are produced by B cells and are defined functionally by the antigen with which they react, and by their subtype, termed "isotypes" (IgM, IgG, IgE, IgD, and IgA; Table 12-4). Thus, an IgM antibody directed against sheep red blood cells (sRBCs) is called anti-sRBC IgM. Because the immune system

Table 12-4

Properties of Immunoglobulin Classes and Subclasses

CLASS	MEAN SERUM CONCENTRATION (MG/ML)	HUMAN HALF-LIFE (DAYS)	BIOLOGICAL PROPERTIES
IgG			Complement fixation (selected subclasses) Crosses placenta
IgG ₁	9	21	
IgG ₂	3	20	
IgG ₃	1	7	
IgG ₄	1	21	
IgA	3	6	Secretory antibody
IgM	1.5	10	Complement fixation Efficient agglutination
IgD	0.03	3	Possible role in antigen-triggered lymphocyte differentiation
IgE	0.0001	2	Allergic responses (mast-cell degranulation)

Figure 12-5. *Ig structure.* Igs are comprised of two heavy chains and two light chains, which are connected by disulfide bonds. Orange areas are variable regions and green areas at top are antigen recognition regions.

Finally, the five types of Ig are dependent on which heavy chain constant region is transcribed and translated (heavy chain genes μ , γ , ϵ , δ , or α encode for the IgM, IgG, IgE, IgD, or IgA heavy chain proteins, respectively).

The variable regions, which are contained within the Fab regions of the antibody molecule, determine antibody specificity and interact with antigen (Fig. 12-5). The Fc region mediates various effector functions, such as complement activation (IgM and some IgG subclasses) and phagocyte binding (via Fc receptors). Antibodies possess several functions: (1) opsonization, which is coating of a pathogen with antibody to enhance Fc receptor-mediated endocytosis by phagocytic cells; (2) initiation of the classic pathway of complement-mediated lysis; (3) neutralization of viral infection by binding to viral particles and preventing further infection; and (4) enhancement of the specificity of effectors of cell-mediated immunity (CMI) by binding to specific antigens on target cells, which are then recognized and eliminated by effector cells such as natural killer (NK) cells or cytotoxic T lymphocytes (CTLs).

Complement One of the consequences of antigen–antibody binding is initiation of the classical pathway of complement-mediated lysis (reviewed by Stoermer and Morrison, 2011). The complement system is a series of about 30 serum proteins whose primary functions are the destruction of membranes of infectious agents and the promotion of an inflammatory response (see the “Inflammation” section). Complement activation occurs with each component sequentially acting on others, in a manner similar to the blood-clotting cascade (Fig. 12-6). Proximal components of the cascade are often modified serine proteases, which activate the system but have limited substrate specificity. Several components are capable of binding to microbial membranes and serve as ligands for complement receptors associated with the membrane. The final components, which are related structurally, are also membrane-binding proteins that can enter into the membrane and disrupt membrane integrity, termed the membrane attack complex (MAC).

Specifically, three pathways have been identified in activation of the complement cascade. The classical complement pathway is initiated when antibody binds antigen on the microorganism. The classical pathway then proceeds by activating a C1 subunit serine protease, subsequently recruiting C4, C2, and C3. Various cleavages ultimately result in C3b surface binding to the microorganism and

generates antibodies to thousands of antigens with which the host may or may not ever come into contact, antibodies of unknown specificity are referred to as immunoglobulin (eg, serum immunoglobulin or serum IgM) until they can be defined by their specific antigen (eg, anti-sRBC IgM).

The ability of the immune system to generate antibody to thousands of antigens is the result of somatic recombination, in which the germline DNA that encodes for antibodies is rearranged in B cells. All Igs are made up of heavy and light chains and of constant and variable regions. For the light chain genes, two separate gene segments (V and J) are combined to form the variable region, which is then joined to one constant region. For the heavy chain genes, three separate gene segments (V, D, and J) are combined to form the variable region, which is then joined to one constant region. There are several light chain V and J genes, and several heavy chain V, D, and J genes, which when rearranged in various combinations, contribute to the immense genetic diversity of the Ig genes (Fig. 12-4).

Figure 12-4. *Ig recombination.* An example of VDJ recombination that might occur for Ig heavy chain in B cells or TCR β chain in T cells. Ig light chain in B cells or TCR α chain in T cells is similar, but does not include D genes.

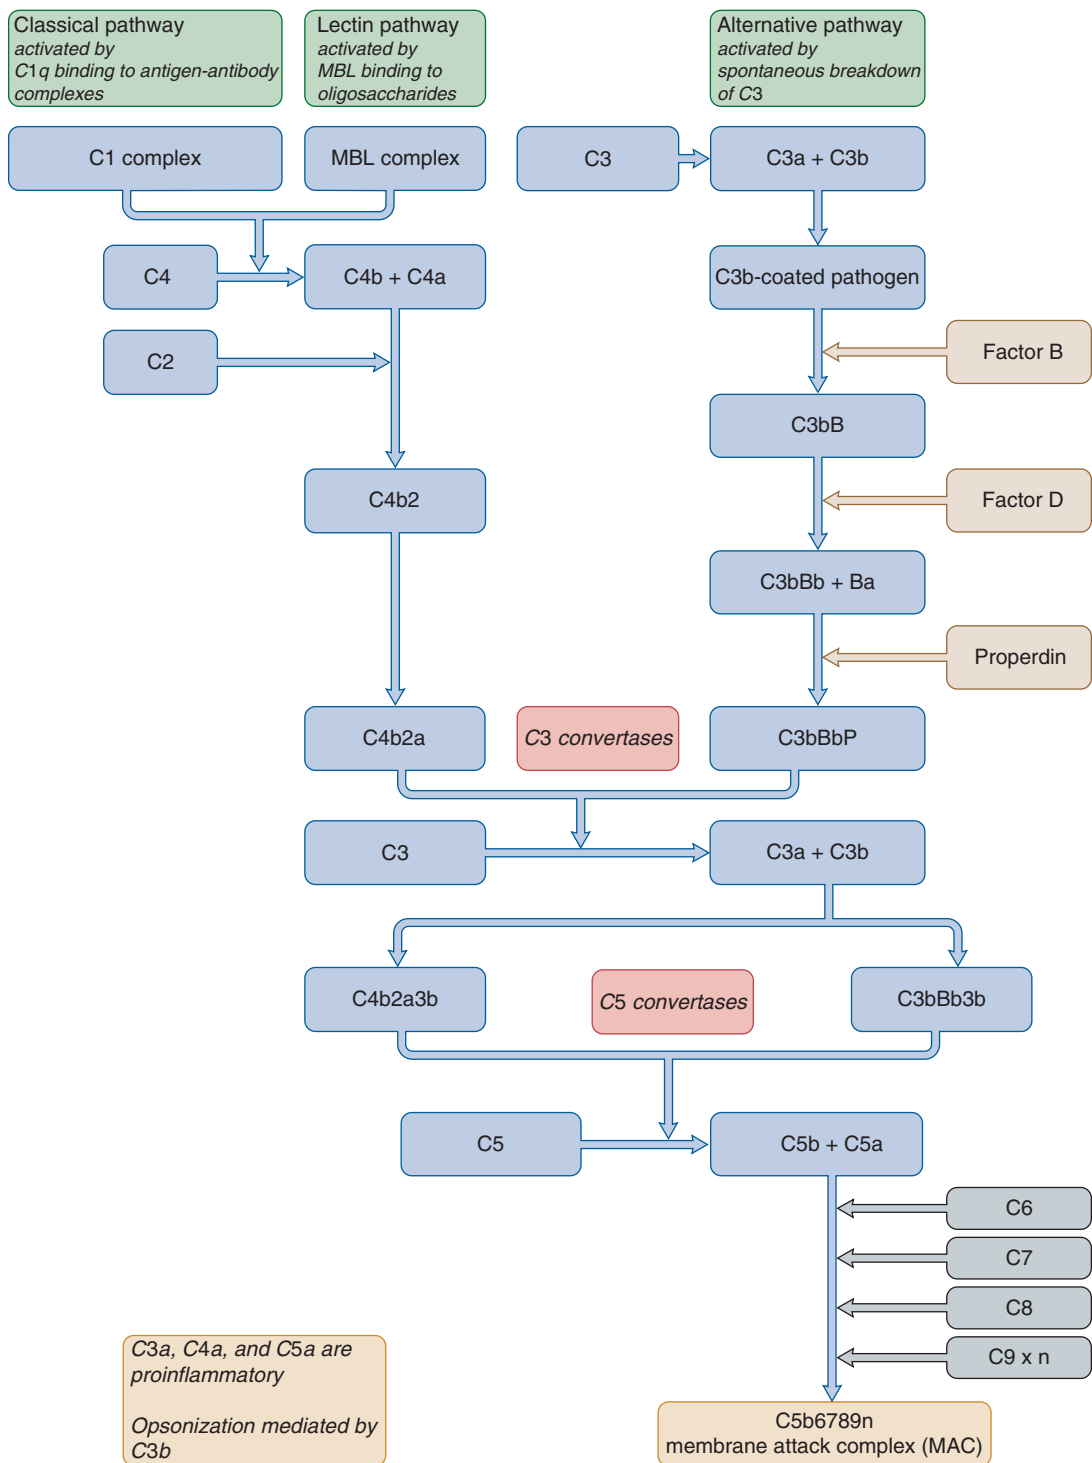

Figure 12-6. The complement cascade. The complement cascade can be activated in three different ways. Cytolysis occurs via generation of the MAC. Various complement proteins generated along the pathway are either proinflammatory mediators (C3a, C5a) or result in opsonization (C3b).

release of C3a, a proinflammatory mediator (see the “Inflammation” section). Microorganism-bound C3b can then be recognized by complement receptors on phagocytic cells, which engulf and destroy the microorganism. It is also at this point that the alternative pathway can be activated and amplifies the complement-mediated killing of the microorganism. Finally, C3b mediates recruitment of C5, which is cleaved, generating C5b on the surface and releasing C5a, another proinflammatory mediator (see the “Inflammation”

section). Microorganism-bound C5b recruits C6 and C7, the three of which form a complex and recruit C8. C9 is ultimately recruited, polymerizes, and forms a pore in the membrane of the microorganism, causing its death. In addition to the classical and alternative pathways, complement-mediated lysis is also activated through the lectin pathway, in which binding of mannin-binding lectin (MBL) to the surface of the microorganism activates the pathway and converges with the classical pathway at C4 (Fig. 12-6).

A functional outcome of complement activation, in addition to cytolysis and generation of proinflammatory mediators, is opsonization, the process by which microorganisms are altered by opsonins (predominantly IgM and IgG and C3b), rendering them vulnerable to phagocytosis by cells (usually macrophages and neutrophils) (Dunkelberger and Song, 2010). Complement activation results in microorganism-bound C3b. Therefore, in combination with IgG antibodies recognizing extracellular antigens and C3b opsonization, phagocytic cells efficiently engulf the microbe through Fc receptors specific for IgG or complement receptors.

Antigen Processing In order to elicit an acquired immune response to a particular antigen, that antigen must be taken up and processed by accessory cells for presentation to lymphocytes. Accessory cells that perform this function are termed antigen-presenting cells (APCs) and include macrophages, B cells, and dendritic cells (DCs). Of these, the most proficient APC is the DC. There are several subtypes of DC, including plasmacytoid (pDCs), conventional (cDCs; can be resident or migratory depending on whether they migrate to the site of infection), and specialized DCs in the skin called Langerhan's cells. In addition, there are follicular DCs, which predominantly mediate T-cell-independent stimulation of B cells in germinal centers (Vinuesa *et al.*, 2010) and will not be discussed further as they are beyond the scope of this chapter.

In most tissues in the absence of antigenic stimulation, DCs are in an immature state, during which they efficiently capture antigens. DCs can mature in response to antigen itself, toll-like receptor (TLR) agonists such as lipopolysaccharide (LPS), or cytokines (GM-CSF, tumor necrosis factor [TNF- α]) (Banchereau and Steinman, 1998). Upon maturation, DCs migrate to lymph nodes and present antigen to T cells. Thus, the DC–T cell interaction is critical for the development of an acquired immune response.

Immature DCs internalize the antigen either by phagocytosis, pinocytosis, or by receptor-mediated endocytosis (via antigen, Fc, or complement receptors), after which the DCs mature to express high levels of both classes of MHC (MHCI and MHCII), which can stimulate both innate and adaptive immune responses, and of costimulatory molecules to facilitate interaction with T cells (Banchereau and Steinman, 1998). Interestingly, Langerhan's cells express high levels of major histocompatibility complex class II (MHCII) even in a resting state (ie, nonactivated) (Kaplan, 2010). Following internalization, antigen is processed (intracellular denaturation and catabolism) through several cytoplasmic compartments, and a piece of the antigen (peptide fragments about 20 amino acids in length) becomes physically associated with MHCII (Fig. 12-7). This MHCII–peptide complex is then transported to the surface of the cell and can interact in a specific manner with T lymphocytes. For most APCs, an immunogenic determinant is expressed on the surface of the APC within an hour after internalization, although this is slightly longer for B cells (three–four hours). In addition to processing and presentation, pieces of processed antigen may be expelled into the extracellular space. These pieces of processed antigen can then bind in the peptide groove of empty MHCII on the surface of other APCs for the presentation of that peptide fragment to lymphocytes.

In addition to antigen processing and presentation via MHCII, some antigens may be processed and presented via MHCI. Although the pathways share some similarities in that short peptide fragments of antigens are generated, loaded onto MHCI, and presented on the surface of cells to T lymphocytes, major differences between the MHCI and MHCII pathways are

Figure 12-7. Antigen processing by the MHCII pathway. Antigen is engulfed by an APC (DC, macrophage, or B cell), degraded, and loaded onto MHCII. The MHCII–peptide complex is then expressed on the surface of the APC for presentation to CD4⁺ T cells.

(1) antigens processed and presented via MHCI are not limited to professional APC; (2) all nucleated cells express MHCI; (3) the mechanisms by which the antigen is processed and loaded onto MHCI are slightly different than MHCII; (4) the MHCI antigenic peptides are usually smaller, often 8 to 10 amino acids in length; (5) the MHCI antigens to be processed are usually aberrantly expressed proteins, such as viral-associated proteins or mutated proteins; (6) MHCI facilitates antigen presentation to CD8⁺ T cells, whereas MHCII facilitates antigen presentation to CD4⁺ T cells. MHCI antigen processing and presentation is the major pathway by which virally infected cells are detected and killed by the acquired immune system.

Regardless of the MHC utilized to present antigens to lymphocytes, T cells are able to recognize antigen in the context of MHC with their T-cell receptor (TCR). Similar to Ig, the ability of T cells to specifically recognize thousands of antigens is due to somatic recombination. All TCRs are comprised of two different subunits, each encoded from a distinct gene (most abundant T-cell population expresses $\alpha\beta$, but $\gamma\delta$ also exist). All TCR subunits are made up of constant and variable regions. For α subunits, two separate gene segments (V and J) are combined to form the variable region, which is then joined to one constant region. For β subunits, three separate gene segments (V, D, and J) are combined to form the variable region, which is then joined to one of the two constant regions. Similar to the Ig genes, there are several light chain V and J genes, and several heavy chain V, D, and J genes (Fig. 12-4).

With regard to T and B cells, key events that occur following antigen encounter are (1) specific antigen recognition either in the context of MHCI or MHCII for T cells or through the Ig receptor for B cells; (2) cellular activation and initiation of intracellular signaling cascades that contribute to production and release of cytokines and other cellular mediators; (3) clonal expansion (proliferation) of antigen-specific cells; and (4) differentiation of antigen-stimulated lymphocytes into effector and memory cells.

Innate Immunity

As stated above, innate immunity acts as a first line of defense against anything nonself. With respect to infectious agents, the innate immune system eliminates most potential pathogens before significant infection occurs. The innate immune system

includes physical and biochemical barriers both inside and outside the body, as well as immune cells designed for host defense responses.

Externally, the skin provides an effective barrier, as most organisms cannot penetrate intact skin. Most infectious agents enter the body through the respiratory system, gut, or genitourinary tract. Innate defenses present to combat infection from pathogens entering through the respiratory system include mucus secreted along the nasopharynx, the presence of lysozyme in most secretions, and cilia lining the trachea and main bronchi. In addition, reflexes such as coughing, sneezing, and elevation in body temperature are also a part of innate immunity. Pathogens that enter the body via the digestive tract are met with severe changes in pH (acidic) within the stomach and a host of microorganisms living in the intestines.

Cellular Components: Neutrophils, Macrophages, Dendritic Cells, Natural Killer Cells, NKT Cells, and $\gamma\delta$ T Cells Several cell types are involved in innate immunity, and in fact, some also provide critical signals to initiate adaptive immune responses (Tables 12-3 and 12-5). Neutrophils (also known as polymorphonuclear cells or PMNs) are phagocytic cells that develop from the myeloid lineage of HSCs. Neutrophils enter the bloodstream where they circulate for about 10 hours and then enter the tissues where they perform effector functions for about one to two days. Neutrophils are capable of passing between (ie, extravasation) the endothelial cells of the blood vessels and thereby represent a primary line of defense against infectious agents. They are excellent phagocytic cells and can eliminate most microorganisms through the release of various

reactive oxygen species (ROS), such as superoxide, singlet oxygen, ozone, hydrogen peroxide, and hydroxyl radicals. Their phagocytic activity is greatly enhanced by the presence of complement and antibody deposited on the surface of the foreign target. They are also important in the induction of an inflammatory response (see the “Inflammation” section).

Also important in the inflammatory response are macrophages. Macrophages are terminally differentiated monocytes, which develop from the myeloid lineage of HSCs. Upon exiting the bone marrow, monocytes circulate within the bloodstream for about one day. At that time, they begin to distribute to the various tissues where they can then differentiate into macrophage subsets. Tissue-specific macrophages include Kupffer cells (liver), alveolar macrophages (lung), microglial cells (CNS), and peritoneal and splenic macrophages. These tissue-specific macrophages have distinct properties and vary in the extent of surface receptors, oxidative metabolism, and expression of MHCII, due to the factors present within the microenvironment in which the monocyte differentiates. Macrophages can be classified as classically activated macrophages (M1), which are proinflammatory and participate in antigen presentation, or alternatively activated macrophages (M2), which do not present antigen well, but are efficient in apoptotic cell removal (reviewed by Martinez *et al.*, 2008). Thus, M1 macrophages are also considered APCs.

A more proficient APC is the DC, which was introduced above in the “Antigen Processing” section. DCs are a critical part of innate immunity since they survey their environment for pathogens, then mature to become highly efficient APCs. Thus, they provide a critical bridge between initial detection of an infectious

agent and elicitation of T-cell responses. DCs can be classified into several subsets and it is thought that the various subsets develop from either CLPs or CMPs, although the exact details are still not clear (reviewed by Watowich and Liu, 2010). Although not reviewed here, part of the challenge with lineage definition is due to extensive heterogeneity of cell surface protein expression of DC subsets, including varying expression of CD11b, CD11c, MHCII, CD4, CD8, and CD205 (reviewed by Watowich and Liu, 2010). All DCs possess efficient APC activity and cytokine production (Watowich and Liu, 2010), but may also possess specialized functions (pDC, for instance, secrete large amounts of Type I interferons (IFNs), such as IFN- α , which is necessary for T-cell differentiation) (Sachdeva *et al.*, 2008).

Like other immune cells, NK cells are derived from a HSC. NK cells are part of a larger family of cells defined as innate lymphoid cells (iLCs), which play roles in innate immunity and inflammation, particularly during the initial phases of inflammation prior to T-cell differentiation (Spits and Di Santo, 2011; Vanaudenaerde *et al.*, 2011). There are two major NK functions: cytokine production and cytotoxicity. NK cells are a predominant producer of IFN- γ , which helps mature DC (Vivier *et al.*, 2011). Thus, NK cells also facilitate the innate-adaptive immunity bridge. NK cells mediate both antibody-independent and antibody-dependent cellular cytotoxicity (ADCC) using a variety of mechanisms, including perforin and granzyme, Fas L, TRAIL, and TNF- α . ADCC occurs via the Fc γ RIIIA, which is present on most NK cell subsets. NKT cells are one such subset of NK cells that express both NK- and T-cell markers, including Cd1d, which allows the NKT cell to present self and exogenous antigenic glycolipids (Diana and Lehuen, 2009).

Another cell type that has recently been shown to facilitate the innate-adaptive immunity bridge is the $\gamma\delta$ T cell. These cells migrate predominantly to “exposed” tissues, including skin, lung, gut, and reproductive organs, and are also expressed highly in the liver (Bonneville *et al.*, 2010). In part through the expression of TLRs, which are discussed in more detail below, $\gamma\delta$ T cells can acquire effector functions, which are not unlike NK cells (cytokine production and cytotoxicity). There is also a subpopulation of B cells (ie, CD5⁺ or B-1 cells) that also bridge innate and adaptive immunity. Unlike the conventional B-2 cells, B-1 cells predominate in embryonic life and are later found mostly in the peritoneal and pleural cavities. B-1 cells are self-renewing and spontaneously produce polyspecific IgM antibodies (ie, natural antibodies) independent of T-cell help (Baumgarth, 2011).

Historically, innate immunity was defined as nonspecific. It is clear, however, that innate cells express receptors that respond to soluble components (eg, Fc or complement receptors) or to certain antigenic motifs. Pattern recognition receptors are a family of receptors that recognize pathogen-derived molecules or cell-derived molecules produced in response to cellular stress (“danger” molecules). Receptors that recognize pathogen-associated molecular patterns (PAMPs) are TLRs; receptors that recognize danger-associated molecular patterns (DAMPs) include NOD-like receptors (NLR) and RIG-like receptors (RLR) (Davis *et al.*, 2011). Several TLRs are expressed extracellularly, and several are expressed intracellularly in endosomes. This diverse localization allows cells to respond to a variety of pathogenic components, such as bacterial cell wall lipids, single- and double-stranded nucleic acids, or fungal and parasitic products (Chang, 2010). Functional consequences of TLR engagement on cells include expression of adhesion molecules, chemokines or cytokines to stimulate T- or B-cell differentiation, enhance phagocytosis, or maturation of DC (Chang, 2010).

NLRs or RLRs that recognize DAMPs are expressed on many innate cells. Several family members of NLRs participate in a complex called the inflammasome, which activates inflammatory caspases to enhance production of mature interleukin (IL)-1 β and IL-18 (Martinon *et al.*, 2009).

A common effector mechanism for many immune cells, including innate cells, is cytokine or chemokine production. Although a partial list of cytokines and a brief description of the cell types that release and are acted upon by these various mediators is provided in Table 12-6, there are also several shared characteristics of cytokines, chemokines, and IFNs that merit discussion for the purposes of understanding immunotoxicological mechanisms. First, the primary function of cytokines, chemokines, and IFNs is cell–cell communication. The resulting actions by cells receiving messages in the form of cytokines, chemokines, or IFNs are diverse and include cellular activation, initiation or termination of intracellular signaling events, proliferation, differentiation, migration, trafficking, or effector functions. Second, although some of these molecules might be constitutively expressed, most are inducible in response to antigens, cellular stressors, or other cytokines. Thus, many cytokines, chemokines, and IFNs are not stored in the cell, but rather are tightly regulated, often at the transcriptional level, so that they are quickly generated on demand. An example of a cytokine important in innate immunity is IL-1, which is rapidly transcribed in response to various stimulants using the critical transcription factor nuclear factor kappa B (NF- κ B). Third, many cytokines share common receptor subunits such that should one particular subunit of a receptor be adversely affected by an immunotoxic agent, the functional outcome might be amplified. An example would be the common γ chain, which is shared by the IL-2, IL-4, IL-7, IL-9, IL-13, IL-15, and IL-21 receptors. Although a compound might “only” affect transcription of the common γ chain, the immunological consequences of affecting this target could be quite destructive.

Other soluble components of innate immunity include the complement cascade, acute-phase proteins, granzyme and perforin, and various cytokines, chemokines and IFNs. Although the complement cascade is described elsewhere in this chapter (see “Antigen Recognition” and “Inflammation” sections), it is also important in innate immunity because of its activation through the lectin pathway. Furthermore, C3a and C5a, which are chemokines generated during the cascade, recruit phagocytic cells to the site of complement activation. Acute-phase proteins, such as serum amyloid A, serum amyloid P, and C-reactive protein, participate in an acute-phase response to infection by binding bacteria and facilitating complement activation. Granzyme and perforin work in conjunction, with perforin disrupting the target cell membrane, allowing granzyme to enter and mediate cell lysis by several mechanisms.

Acquired (Adaptive) Immunity

If the primary defenses against infection (innate immunity) are breached, the acquired arm of the immune system is activated and produces a specific immune response to each infectious agent, which usually eliminates the infection. This branch of immunity is also capable of remembering the pathogen and can protect the host from future infection by the same agent. Therefore, the two key features that define acquired immunity are specificity and memory. Acquired immunity may be further subdivided into humoral and CMI. Humoral immunity is directly dependent on the production of antigen-specific antibody by B cells and involves the coordinated

Table 12-6

Cytokines: Sources and Functions in Immune Regulation

CYTOKINE	SOURCE	PHYSIOLOGICAL ACTIONS
IL-1	Macrophages Epithelial cells	Activation and proliferation of T cells Proinflammatory Induces fever and acute-phase proteins Induces synthesis of proinflammatory cytokines
IL-2	T cells	Primary T-cell growth factor Growth factor for B cells and NK cells
IL-4	Th2 cells Mast cells	Proliferation of activated Th2 and B cells B-cell differentiation and IgE isotype switching Antagonizes IFN- γ Inhibits Th1 responses
IL-5	Th2 cells Mast cells	Proliferation and differentiation of eosinophils
IL-6	Macrophages Th2 cells B cells Endothelial cells	Enhances B-cell differentiation and Ig secretion Induction of acute-phase proteins by liver Proinflammatory Proliferation of T cells and increased IL-2 receptor expression
IL-10	Tregs Bregs Macrophages	Inhibits T-cell and macrophage responses
IL-12	DCs Macrophages	Activates NK cells Induces Th1 responses
IL-13	Th2 cells	Stimulates B-cell growth Inhibits Th1 responses
IL-17	Th17 cells NK cells $\gamma\delta$ T cells Neutrophils	Proinflammatory Inhibits Tregs
IFN- α/β (Type I IFN)	Leukocytes DCs Fibroblasts	Induction of MHCI expression Antiviral activity Stimulation of NK cells
IFN- γ	T cells NK cells	Induction of MHCI and MHCII Activates macrophages
TGF- β	Macrophages Megakaryocytes T cells	Enhances monocyte/macrophage chemotaxis Enhances wound healing: angiogenesis, fibroblast Proliferation, deposition of extracellular matrix Inhibits T- and B-cell proliferation Inhibits antibody secretion Primary inducer of isotype switch to IgA
GM-CSF	T cells Macrophages Endothelial cells Fibroblasts	Stimulates growth and differentiation of monocytes and granulocytes

interaction of APCs, T cells, and B cells. CMI is that part of the acquired immune system in which effector cells, such as phagocytic cells, helper T cells, regulatory T cells, APCs, cytotoxic T cells, or T memory cells, play the critical role(s) without antibody involvement.

Cellular Components: Antigen-Presenting Cells, T Cells, and B Cells APCs, which were discussed previously in the “Antigen Processing” section, include professional APCs such as

B cells, macrophages, and DC. Although all cells may act as APCs with internal antigen processing through the MHCI pathway, what distinguishes a professional APC from the others is the ability to internalize external antigens and process them through the MHCII pathway for presentation to T cells.

B cells are not only capable of serving as professional APCs, but they are also the effector cells of humoral immunity, producing a number of Ig isotypes with varying specificities and affinities.

Like other immune cells, the B cell develops in the bone marrow from the HSC and becomes committed to the B-cell lineage when the cell begins to rearrange its Ig genes, as described in the “Antigen Recognition” section (Figs. 12-3 and 12-4). Following successful Ig rearrangement, these cells express heavy chains in their cytoplasm and are termed pre-B cells. Expression of membrane IgM and IgD indicates a mature B cell. B cells expressing CD5 (termed B-1 cells) predominate in embryonic life and are later found mostly in the intestinal mucosa (Hardy, 2006). These cells are probably associated with innate immunity and are long-lived, self-renewing cells that produce high levels of polyspecific IgM, much of which are autoantibodies suggesting a possible role of B-1 cell subtype in autoimmunity (Baumgarth, 2011). Mature B cells of the conventional B-2 subset are found in the lymph nodes, spleen, and peripheral blood. Upon antigen binding to surface immunoglobulin (part of the B-cell receptor [BCR]), the mature B cell becomes activated and, after proliferation, undergoes differentiation into either a memory B cell or an antibody-forming cell ([AFC]; also known as a plaque-forming cell [PFC]) that actively secretes antigen-specific antibody. A broad description of several B-cell characteristics can be found in Table 12-5.

At a specified time following their commitment to the T-cell lineage, T-cell precursors migrate from the bone marrow to the thymus where, in a manner analogous to B cells, they begin to rearrange their TCRs, as described in the “Antigen Recognition” section (Fig. 12-3). The TCR consists of two chains, either $\alpha\beta$ or $\gamma\delta$. The majority of T cells express the $\alpha\beta$ TCR, which is critical for the recognition of antigens in the context of MHC. A much smaller population of T cells express a $\gamma\delta$ TCR. The $\gamma\delta$ T cells differ from $\alpha\beta$ T cells in that they do not require antigen processing or presentation by MHC but instead directly bind intact host and pathogen proteins. Like the B-1 lineage, the $\gamma\delta$ T cells are expressed first in embryonic development and may be associated with innate immunity (see the “Innate Immunity” section). T cells committed to the $\alpha\beta$ lineage will express the surface marker cluster of differentiation antigens (CD) 4 and 8. CD4 and CD8 are coreceptors expressed by $\alpha\beta$ T cells and are involved in the interaction of the T cell with MHC. T cells expressing $\alpha\beta$ TCR and both CD4 and CD8 are termed immature double-positive cells ($CD4^+/CD8^+$). These immature cells then undergo positive and negative selection to (1) eliminate cells that do not produce a functional TCR or produce TCRs with no affinity for self-MHC (positive selection); or (2) eliminate cells that strongly bind MHC plus self-peptide (negative selection). Double-positive cells that survive positive and negative selection will give rise to NKT cells or T cells that lose expression of either CD4 or CD8 and enter the periphery as mature single-positive cells ($CD4^+$ or $CD8^+$) with a high level of $\alpha\beta$ TCR expression. This rigorous selection process produces T cells that can recognize MHC plus foreign peptides and eliminates autoreactive T cells. Additionally, expression of CD4 or CD8 will determine to which MHC class the $\alpha\beta$ TCR will bind. CD4 will facilitate binding to MHCII expressed on APCs; T cells expressing CD4 (helper T cells, Th) help activate other cells of the adaptive immune response. CD8 will facilitate binding to MHCI, which is expressed on all nucleated cells; generally, T cells expressing CD8 mediate cell killing (CTL). A broad description of several T-cell characteristics (specific to $\alpha\beta$ T cells) can be found in Table 12-5. In contrast to $\alpha\beta$ T cells, the $\gamma\delta$ T cells do not express CD4 or CD8 and therefore do not interact with MHC and do not undergo positive or negative selection. Since $\gamma\delta$ T cells are not negatively selected for autoreactivity, these cells may be associated with the development of hypersensitivity and autoimmunity.

Figure 12-8. The cytokine environment drives different Th populations. Various Th cells (and T regulatory cells, Tregs) are differentially induced in response to the cytokine milieu. Th1 cells drive CTL responses; Th2 cells drive humoral immune responses; Th9, Th17, and Th22 all produce proinflammatory cytokines; Tregs control other T-cell responses.

Mature T cells are found in the lymph nodes, spleen, and peripheral blood. Upon binding of the TCR to MHC plus antigen, the mature T cell becomes activated and, after proliferation, undergoes differentiation into either an effector cell or a memory T cell. Effector Th cells can subsequently differentiate into several phenotypes depending on the cytokine milieu (Fig. 12-8), two of which, Th1 and Th2, dictate whether CMI or humoral immunity will predominate, respectively. Th1 cells predominantly express IL-2, IFN- γ , and lymphotoxin, which promote CMI and humoral defense against intracellular invaders. Th2 cells predominantly express IL-3, IL-4, IL-5, IL-6, IL-10, and IL-13, which promote humoral defense against extracellular invaders. Although the two populations are not mutually exclusive, they do negatively regulate each other, such that a strong Th1 response suppresses a Th2 response and vice versa.

Th17, Th9, and Th22 cells have been shown to be critical for inflammatory responses (see the “Inflammation” section), and several studies including autoimmune models and clinical studies support a role of Th17 cells in inflammation and autoimmune diseases. Modulation of Th17 cellular function by xenobiotics may alter these disease states. Conversely, a better understanding of the relationship between Th17 and specific disease states may lead to new therapeutics in the treatment of autoimmune and inflammatory diseases (Hemdan *et al.*, 2010; Kimura and Kishimoto, 2011).

The ability of APCs, B cells, and T cells to communicate with each other is dependent on a variety of receptor–ligand interactions between cell types. These interactions also help dictate the type of immune response (ie, humoral vs. CMI) and the magnitude of the immune response. For example, TCR binding by antigen presented in the context of MHC is the major interaction that must occur between APCs and T cells to initiate an acquired immune response. Subsequent to this initial interaction, costimulatory molecules must be engaged on both the T cells and APCs to sustain and direct the immune response. One of the best-characterized interactions occurs between CD28 on the T cells and CD80 or CD86 (B7.1 and B7.2) on the APCs, which provides a more robust immune response as measured by clonal expansion and cytokine (eg, IL-2) production. Later in the response (two–three days), T cells express CTLA-4, which exhibits higher affinity for CD80/CD86 than does CD28, and

Thymus-derived (nTreg)
Peripheral (iTreg)

Figure 12-9. *Tregs and Bregs.* There are at least three different subpopulations of Tregs and Bregs, all of which suppress immune function via IL-10 or TGF- β . Tregs can be natural (thymus-derived) or induced in the periphery.

the CTLA-4-CD80/CD86 interaction serves to suppress the T-cell response. Other important interactions between APCs and T cells include CD40 and CD40 ligand (CD40L), which sustains clonal expansion and differentiation of the T cells and provides activation signals to the APC; inducible T-cell costimulator (ICOS [CD278], a member of the CD28-superfamily) and ligand for ICOS, which sustains clonal expansion and differentiation of the T cells and induces IL-10 production; and 4-1BB (CD137/Ly63, a member of the TNF receptor superfamily) and 4-1BB ligand, which sustains clonal expansion of the T cells and helps to activate the APC (CD40 ligand, ICOS, and 4-1BB are expressed on T cells). Therapeutic agents that bind some of these costimulatory surface molecules have been developed and utilized clinically to suppress immune function for transplantation and autoimmune therapy, which will be discussed in “Therapeutic Agents” under the “Immune Modulation by Xenobiotics” section. For simplicity, in figures throughout the chapter, only the CD28-B7 interaction is depicted.

The duration and extent of an acquired immune response is also controlled by specialized regulatory cells found in both the T-cell and B-cell lineages, and there are considerable functional similarities between the different regulatory subsets found within both lineages (reviewed by Noh and Lee, 2011) (Figs. 12-8 and 12-9). For the T-cell lineage, there is a small population of CD4⁺ cells that develop into T-regulatory cells (Tregs), which help to control various immune responses, including those directed against self. Tregs are generally identified as CD4⁺CD25⁺Foxp3⁺, which are defined as natural Tregs if they develop in the thymus (Lio and Hsieh, 2011), but can also be induced in the periphery in response to IL-2 and TGF- β (Horwitz *et al.*, 2008). Tregs can suppress CD4⁺ and CD8⁺ IL-2 production and proliferation, and *in vivo* have been shown to suppress autoimmune disease (Sakaguchi *et al.*, 2009). The mechanisms by which Tregs suppress immune responses involve direct Treg-cell contact since Tregs are unable to suppress immune function when separated from the target cell population by a semipermeable membrane or when Treg-conditioned medium is used (Takahashi *et al.*, 1998; Thornton and Shevach, 1998). Immune suppression by Tregs is likely a multistep process, which might involve direct cell killing via granzyme or perforin, induction of intracellular cAMP, or affecting cell surface expression of critical proteins, such as CD80/CD86. For instance, Foxp3 induces high levels of CTLA-4, which would interact with target cell CD80/CD86 and prevent target cell CD80/CD86 from interacting with CD28 on other stimulatory cells (reviewed by Sakaguchi *et al.*, 2009). It has also been suggested that the high expression level of CD25 on Tregs

might act as a reservoir for IL-2 in an immune synapse microenvironment, thereby preventing IL-2 from stimulating surrounding cells (Sakaguchi *et al.*, 2009). In addition to Tregs, other regulatory T-cell subsets have been identified such as the IL-10 producing Tr1 cells and the TGF- β producing Th3 cells; all three regulatory subsets appear to be involved in regulating immune responses (Noh and Lee, 2011). Regardless of the processes that direct Treg (or perhaps Tr1 and Th3) suppression of immune function, their induction has been identified as one mechanism by which drugs and xenobiotics might result in immune suppression (Marshall and Kerkvliet, 2010; Ohkura *et al.*, 2011). Like the regulatory T cells, several subsets of regulatory B cells are emerging and several recent reviews have been devoted to outlining the experimental evidence for specific regulatory B-cell subpopulations and their generally suppressive role in hypersensitivity and autoimmune diseases (DiLillo *et al.*, 2010; Mauri, 2010; Noh and Lee, 2011). Although phenotypically diverse, regulatory B cells appear to have arisen from the CD5 B-1 population (briefly described above). Noh and Lee (2011) have described three subsets of regulatory B cells based on cytokine or Foxp3 expression, which include Br1 or B10 cells that produce IL-10, Br3 that produce TGF- β , and Breg that express Foxp3. These subsets resemble the regulatory T-cell subsets, Tr1, Th3, and Treg, respectively (Fig. 12-9 adapted from Noh and Lee, 2011). The regulatory T- and B-cell subsets also appear to reciprocally activate or suppress each other and may cooperatively control immune responses. The interplay between regulatory T- and B-cell subsets and their impact on immune responses, including autoimmune and hypersensitivity diseases, are important areas of investigation that will likely lead to a better understanding of immune pathologies including those induced by drugs and other xenobiotics.

Humoral and Cell-Mediated Immunity As described earlier, there are two branches of acquired immunity, humoral immunity, and CMI. Humoral immunity is that part of the acquired immune system in which antibody is involved. In general, B cells produce antibodies specific to an antigen, which may act to opsonize or neutralize the invader, or the antibodies act to recruit other factors, such as the complement cascade. CMI is that part of the immune system in which various effector cells perform a wide variety of functions to eliminate invaders. Often, these two branches are coordinated, such as activation of Th cells that produce specific cytokines that enhance B-cell proliferation and differentiation to secrete more antibody. A general diagram of the cellular interactions involved in a humoral immune response is given in Fig. 12-10. The production of antigen-specific IgM requires three to five days after the primary (initial) exposure to antigen (Fig. 12-11). Upon secondary antigenic challenge, the B cells undergo isotype switching, producing primarily IgG antibody, which is of higher affinity for the activating antigen. In addition, there is a higher serum antibody titer associated with a secondary antibody response. CMI functions include delayed-type hypersensitivity (DTH) and cell-mediated cytotoxicity. Cell-mediated cytotoxicity responses may occur in numerous ways: (1) MHC-dependent recognition of specific antigens (such as viral particles or tumor proteins) by CTL (Fig. 12-12); (2) indirect antigen-specific recognition by the binding of Fc receptors on NK cells to antibodies coating target cells; and (3) receptor-mediated recognition of complement-coated foreign targets by macrophages. Many of these are described in more detail in “Hypersensitivity” under the section entitled “Immune-Mediated Disease”

In cell-mediated cytotoxicity, the CTL or NK effector cell binds in a specific manner to the target cell. The majority of CTLs express CD8 and recognize either foreign MHCI on the surface of allogeneic cells, or antigen in association with self-MHCI (eg, viral

Figure 12-10. Cellular interactions in the humoral immune response. Antigen is engulfed by an APC (usually DC) and the antigenic peptide is presented to CD4⁺ T cells in the context of MHCII. CD4⁺ T cells then become activated, proliferate, and differentiate into Th cells, which release cytokines to help B cells that had also encountered the same antigen. B cells then become activated, proliferate, and differentiate into memory B cells or antigen-producing plasma cells.

particles). Fig. 12-12 shows the cell-mediated CTL response. NK cell recognition of target cells is also antigen-specific because the mechanism of recognition involves binding of Fc receptors on NK cells to the Fc portion of antigen-specific antibody that coats the target cell; a process referred to as ADCC. Once the CTL or NK cells interact with the target cell, the effector cell undergoes cytoplasmic reorientation so that cytolytic granules are oriented along the side of the effector, which is bound to the target. The effector cell then releases the contents of these granules onto the target cell. The target cell may be damaged by the perforins or enzymatic contents of the cytolytic granules. In addition, CTLs induce the target to undergo apoptosis through activation of the Fas and cytotoxic cytokine (ie, TNF and lymphotoxin) pathways. Once it has degranulated, the effector cell can release the dying target and move on to kill other target cells. Notably, many of the soluble factors critical to the innate immune system are also primary effectors in the acquired immune system, including ROS, granzyme, perforin, cytokines, and IFNs, again demonstrating the interplay among the various arms of the immune system.

Figure 12-11. Kinetics of humoral immune responses. In response to primary antigen encounter, IgM is produced within several days. In response to secondary antigen encounter, IgG is produced more rapidly, and to a higher magnitude, than IgM.

Figure 12-12. Cellular interactions in the CTL response. Antigen is engulfed by an APC (usually DC) and the antigenic peptide is presented to CD4⁺ and CD8⁺ T cells in the context of MHCII and I, respectively. CD4⁺ T cells then become activated, proliferate, and differentiate into Th cells, which release cytokines to help CD8⁺ T cells that had also encountered the same antigen. Especially in the presence of IL-12 produced by the DC, CD8⁺ T cells become activated, proliferate, and differentiate into CTL that can kill other antigen-infected cells.

Inflammation

Inflammation, simply defined, refers to a complex reaction to injury, irritation or foreign invaders characterized by pain, swelling, redness, and heat. Inflammation involves various stages, including release of chemotactic factors following the insult, increased blood flow, increased capillary permeability allowing for cellular infiltration, followed by either an acute resolution of tissue damage or persistence of the response that might contribute to fibrosis or subsequent organ failure (Serhan and Savill, 2005). It is important to emphasize that while inflammation is a natural reaction to repair tissue damage or attack foreign invaders, the process often results in destruction of adjacent cells and/or tissues. Thus, there is overwhelming evidence that inflammation plays a critical role in many diseases, including asthma, multiple sclerosis, cardiovascular disease, Alzheimer's disease, bowel disorders, and cancer. In addition, inflammation exacerbates idiosyncratic reactions to drugs and other chemicals (reviewed by Ganey *et al.*, 2004).

Cellular Components: Macrophages, Neutrophils, and T Cells

Many of the cellular components described in the sections above are critical to initiation and maintenance of an inflammatory response. Major cellular contributors to an inflammatory response are macrophages, neutrophils, and T cells. Neutrophils are often the first, and most numerous, responders to sites of insult. In response to either host- or pathogen-derived signals, neutrophils secrete chemotactic factors to recruit other proinflammatory cells, such as macrophages, to the area. Recently, it has been demonstrated that IL-17 produced early by various sources, including NKT cells, is a critical proinflammatory cytokine that will rapidly induce neutrophil and macrophage influx to the area of insult (Vanaudenaerde *et al.*, 2011). Macrophages can be activated by a variety of mechanisms at the site of insult, such as activation via TLR, proinflammatory cytokines, or recognition of opsonized particles by Fc receptors or complement receptors. Macrophages and neutrophils also induce apoptosis of cells in the insult area

through the release of nitric oxide and other ROS, resulting in disruption of extracellular structures that compromise tissue structure and function (reviewed by Duffield 2003). Both neutrophils and macrophages are phagocytic cells and can contribute to clearing of apoptotic cells. Later in the inflammatory response, T cells are critical for generating an adaptive immune response. T cells are attracted to the insult area by adhesion molecules and integrins, and are activated in response to antigen presented in the context of MHC, often by a DC. As described above, depending on the signals that the T cell receives from the cytokine milieu, distinct subpopulations of T cells are induced (Fig. 12-8). Chronic inflammatory states are maintained with activation and differentiation of Th2 and Th17, which drive chronic eosinophilic and neutrophilic inflammation, respectively (Jutel and Akdis, 2011). Th9 and Th22 cells also likely contribute to chronic inflammation, but their roles are not yet completely understood.

Of all Th subsets, Th17 cells have certainly been shown to play a critical role in inflammation (Kimura and Kishimoto, 2011). In contrast to cells involved in the innate response (NK or NKT cells, $\gamma\delta$ T cells, or other iLCs) that produce IL-17, Th17 cells are part of the adaptive immune response, and produce IL-17, IL-22, and TNF- α (Vanaudenaerde *et al.*, 2011). They are induced in the presence of IL-6 and TGF- β , conditions that are unfavorable for Tregs, thereby exacerbating the proinflammatory response through suppression of Treg differentiation and chronic neutrophilic infiltration (Awasthi and Kuchroo, 2009). Th17 cells are defined by expression of retinoid-related orphan receptors ROR γ and ROR α . Interestingly, Th17 cells also express high levels of aryl hydrocarbon receptor ([AHR]; Veldhoen *et al.*, 2008), providing an additional cellular target for immune modulation by AHR ligands (see the subsection “Polychlorinated Dibenzodioxins” under “Immune Modulation by Xenobiotics”).

There are several other soluble factors that contribute to inflammation that warrant discussion. In addition to ROS that are released from both macrophages and neutrophils to compromise membrane integrity, a plethora of cytokines and chemokines contribute to the inflammatory process. As mentioned above in the “Innate Immunity” section, some proinflammatory cytokines (IL-1 β and IL-18) are produced in a mature form as a result of the activation of the inflammasome (Martinon *et al.*, 2009). In fact, it has been demonstrated that inflammation as a result of disease (ie, influenza) or toxicity (ie, silicosis) depends on inflammasome activation (Cassel *et al.*, 2008; Ichinohe *et al.*, 2009). An additional discussion for the role of the inflammasome in immune responses to inhaled particles is provided in the subsection “Inhaled Substances” under “Immune Modulation by Xenobiotics” and in Fig. 12-22. The actions of various proinflammatory cytokines include inducing fever or activating T cells and macrophages (IL-1); stimulating B- or T-cell proliferation (IL-6); inducing neutrophilia (IL-17); and increasing vascular permeability or inducing apoptosis (TNF- α). Many proinflammatory cytokines also induce acute-phase proteins, such as C-reactive protein. C-reactive protein binds to several ligands, including phosphatidylcholine on the membranes of cells, Fc receptors, and C1q (part of the complement C1 complex), which activates the classical complement cascade (reviewed by Marnell *et al.*, 2005). Complement participates in inflammation through inappropriate and sustained activation of the cascade, ultimately leading to destruction of cells through the MAC (Fig. 12-6). Furthermore, complement fragments, such as C3a and C5a, act as chemotactic factors to recruit other phagocytic cells to sites of insult (macrophages, neutrophils, eosinophils, or mast cells) or induce degranulation (basophils, eosinophils, or mast cells) (Dunkelberger and Song, 2010). Finally, prostaglandins and other eicosanoids possess various

proinflammatory actions, including increased blood flow and pain (prostaglandin E₂), increase in vascular permeability (prostaglandin I₂), and stimulation of endothelial inflammatory responses (thromboxane A₂) (reviewed by Ricciotti and FitzGerald, 2011). Prostaglandins contribute to hyperalgesia and it is for this reason that cyclooxygenase-2, which converts arachidonic acid to other bioactive prostaglandins, is an attractive therapeutic target to reduce inflammation and pain (see the subsection “Anti-inflammatory Agents” under “Immune modulation by Xenobiotics”).

As mentioned above, it is undisputed that chronic inflammation plays a critical role in many disease states, including asthma, multiple sclerosis, cardiovascular disease, Alzheimer’s disease, bowel disorders, and cancer. Chronic inflammation could result in high circulating levels of proinflammatory cytokines, complement fragments, prostaglandins, and thromboxanes. An inflammatory cascade can be established because many of these mediators induce expression of others (ie, TNF- α induces expression of IL-1 and IL-6 or complement fragment C3a causes chemotaxis of phagocytic cells). Moreover, the sustained presence of proinflammatory cytokines could exacerbate ROS production from neutrophils and macrophages. As seen in the next section, the underlying proinflammatory response also plays a critical role in immune-mediated disease.

Immune-Mediated Disease

As stated earlier, the purpose of the immune system is to preserve the integrity of the individual from disease states, whether infectious, parasitic, or cancerous, through both cellular and humoral mechanisms. In so doing, the ability to distinguish self from non-self plays a predominant role. However, situations arise in which the individual’s immune system responds in a manner producing tissue damage, resulting in a self-induced disease. These disease states fall into two categories: (1) hypersensitivity, or allergy, and (2) autoimmunity. Hypersensitivity reactions result from the immune system responding in an exaggerated or inappropriate manner after repeated exposure to the offending antigen. These reactions have been subdivided by Coombs and Gell (1975) into four types, which represent four different mechanisms leading to tissue damage. In the case of autoimmunity, mechanisms involve a break down in self-recognition resulting in the production of auto-reactive antibodies and/or TCRs recognizing self-antigens as non-self, ultimately culminating in tissue damage and disease.

Hypersensitivity

Classification of Hypersensitivity Reactions One characteristic common to all four types of hypersensitivity reactions is the necessity of prior exposure leading to sensitization in order to elicit a reaction upon subsequent challenge. In the case of Types I, II, and III, prior exposure to antigen leads to the production of allergen-specific antibodies (IgE, IgM, or IgG) and, in the case of Type IV, the generation of allergen-specific memory T cells. Fig. 12-13 illustrates the mechanisms of hypersensitivity reactions as classified by Coombs and Gell. Although not completely understood, regulation of Ig production is dependent in part on the characteristics of the antigen, the genetics of the individual, and environmental factors. The mechanisms of antibody production in hypersensitivity reactions are identical to those described earlier in the chapter (Fig. 12-10). A brief description of the four types of hypersensitivity reactions is presented below.

Type I (Immediate or IgE-Mediated Hypersensitivity) Using penicillin as an example, Fig. 12-14 depicts the major events involved in a Type I hypersensitivity reaction (what most people

Figure 12-13. Overview of classification of hypersensitivity reactions. Hypersensitivity reactions are mediated via T cells and antibody production.

think of as “allergy” and is clinically referred to as “atopy”). Sensitization occurs as the result of dermal exposure to antigens or by exposure to antigens through the respiratory or gastrointestinal tract. Most people would mount an IgM, IgG, or IgA immune response to these antigens and clear them without causing any allergic symptoms. It is unclear why these antigens become allergens in certain individuals who respond by mounting an IgE immune response instead, but appears to involve genetic and/or environmental determinants and likely some type of triggering event (eg, acute pathogen exposure and emotional stress). IgE production is highest in lymphatic tissues that drain sites of exposure (ie, tonsils, bronchial lymph nodes, and intestinal lymphatic tissues, including Peyer’s patches) and is low in the spleen. Compared to other Igs, IgE has a low serum concentration and a short serum half-life (Table 12-4). Once produced, soluble IgE not only binds to local tissue mast cells, but also enters the circulation, where it binds to circulating mast cells, basophils, and tissue mast cells at distant sites. Once an individual is sensitized, reexposure to the antigen results in

Figure 12-14. Type I hypersensitivity reaction. Metabolized penicillin is a hapten that conjugates with a protein. The conjugated hapten cross-links IgE antibodies on mast cells. IgE cross-linking causes mast-cell degranulation and releasing histamine and other proinflammatory mediators.

Figure 12-15. Type II hypersensitivity reactions. In complement-independent cytotoxicity, antigen becomes attached to a normal cell, which can be recognized by IgG. A cell capable of cytotoxicity (CTL, NK cell) binds to IgG via its Fc receptor and kills the antigen-coated cell. In complement-dependent cytotoxicity, antigen becomes attached to a normal cell, which can be recognized by IgG. Complement gets activated by the classical pathway (antigen–antibody complexes) and C3a and C5a bind complement receptors.

binding to IgE on local mast cells and degranulation with the release of preformed mediators and cytokines which recruit and activate circulating eosinophils, basophils, macrophages, and neutrophils leading to the synthesis and release of more cytokines and of leukotrienes and thromboxanes. These mediators promote vasodilation, bronchial constriction, and inflammation. Clinical manifestations can vary from urticarial skin reactions (wheals and flares) to signs of hay fever, including rhinitis and conjunctivitis, to more serious diseases, such as asthma and potentially life-threatening anaphylaxis. These responses may begin within minutes of reexposure to the offending antigen; therefore, Type I hypersensitivity is often referred to as immediate hypersensitivity.

Type II (Antibody-Dependent Cytotoxic Hypersensitivity)

Type II hypersensitivity is IgG or IgM-mediated. The antibody response may be mediated by a foreign antigen attached to the surface of a cell or tissue. Conversely, an antibody response could be mediated by an autoantibody due to a breakdown in tolerance and the resulting response would be part of an autoimmune disease (eg, autoimmune hemolytic anemias and Goodpasture’s syndrome). Fig. 12-15 shows the mechanisms of action for complement-independent and complement-dependent cytotoxic reactions. Tissue damage may result from the direct action of cytotoxic cells, such as macrophages, neutrophils, or eosinophils, linked through the Fc receptor to antibody-coated target cells (complement-independent) or by antibody-induced activation of the classic complement pathway. Complement activation may result in C3b binding to the target cell surface with C3b acting as a recognition site for effector cells. Alternatively, the C5b-9 MAC may be bound to the target cell surface, resulting in direct cell lysis.

Type III (Immune Complex-Mediated Hypersensitivity)

Type III hypersensitivity reactions also involve IgG or IgM. The distinguishing feature of Type III is that, unlike Type II, in which Ig production is against specific cellular or tissue-associated antigen, Ig production is against soluble antigen in the serum (Fig. 12-16). This allows for the formation of circulating immune complexes

Figure 12-16. Type III hypersensitivity reactions. IgG is produced against an antigen and antigen-antibody complexes form, which can become deposited in tissue. Complement gets activated by the classical pathway (antigen-antibody complexes), and platelets also interact with complexes. Following complement-mediated cytolysis, released chemotactic factors attract neutrophils and macrophages, causing additional inflammation and tissue damage.

composed of a lattice of antigen and Ig, which may result in widely distributed tissue damage in areas where immune complexes are deposited. The most common location is the vascular endothelium in the lung, joints, and kidneys. The skin and circulatory systems may also be involved. Pathology results from the inflammatory response initiated by the activation of complement. Macrophages, neutrophils, and platelets attracted to the deposition site contribute to the tissue damage. As with Type II hypersensitivity, responses similar to Type III hypersensitivity can be induced in autoimmune diseases due to autoantibodies directed against soluble antigens such as double-stranded DNA or small nuclear proteins as seen with SLE.

Type IV (Cell-Mediated Hypersensitivity) Type IV, or DTH responses, can be divided into three classes: contact hypersensitivity, tuberculin-type hypersensitivity, and hypersensitivity pneumonitis. The following discussion is focused on contact hypersensitivity using the classical example of contact hypersensitivity seen following poison ivy exposure. Contact hypersensitivity is initiated by topical exposure, and the associated pathology is primarily epidermal. It is characterized clinically by an eczematous reaction at the site of allergen contact and, like Type I through III responses, consists of two phases: sensitization and elicitation. However, in this case sensitization is the result of the development of activated and memory T cells as opposed to antibody production (Figs. 12-17 and 12-18). Sensitization occurs when a hapten penetrates the epidermis and forms a complex with a protein carrier. The hapten-carrier complex is processed by Langerhan's DCs that migrate out of the epidermis to the local lymph nodes. There, the APC presents the processed antigen to CD4⁺ Th cells, leading to clonal expansion and the generation of memory T cells including memory CD8⁺ CTL, (Tc) which appear to play a major role in the elicitation phase.

Upon secondary contact, Langerhan's DCs present the processed hapten-carrier complex to memory CD8⁺ CTL in either the skin or the lymph nodes. These activated T cells then secrete cytokines that bring about further proliferation of T cells and generation of CTLs, as well as increased expression of adhesion molecules on the surface of keratinocytes and endothelial cells in the dermis.

Figure 12-17. Type IV hypersensitivity sensitization. A hapten permeates the epidermis and forms a complex with a carrier protein. The conjugated hapten gets engulfed by Langerhan's cells, which migrate to the lymph node and present antigen to CD4⁺ T cells in the context of MHCII. CD4⁺ T cells activate, proliferate, and differentiate into Th or Tc cells and memory T cells.

Both the expression of adhesion molecules and the secretion of proinflammatory cytokines by T cells and keratinocytes facilitate the recruitment of inflammatory cells into the skin, resulting in erythema and the formation of papules and vesicles. In addition and under certain circumstances, intracellular proteins can be modified by lipid-soluble chemicals that might readily cross the cell membrane. These cells then present modified peptides on their cell surface in conjunction with MHC I molecules. CD8⁺ cytotoxic T cells recognize these foreign peptides and cause tissue damage by either direct cytotoxic action (CTL) or the secretion of cytokines that further promote the inflammatory response.

Autoimmunity Autoimmune disease occurs when the reactions of the immune system are directed against the body's own tissues, and, as with hypersensitivity, is characterized by a genetic susceptibility. Autoimmune diseases may be tissue-specific, where the damage is associated with a specific type of tissue or a specific organ, or tissue-nonspecific, where the signs and symptoms

Figure 12-18. Type IV hypersensitivity elicitation. Upon secondary exposure to the hapten, Langerhan's cells either migrate to the lymph node or directly present antigen to memory T cells. Memory T cells become activated and produce cytokines to stimulate proinflammatory cytokine release from other cell types, such as keratinocytes.

are associated with several organs and tissues. The targets from the perspective of the primary sites of tissue damage in autoimmune disease are many and varied. The following organs, cells, and organelles have all been determined to be the site of autoimmune reactions: nuclei (specifically histones and/or single-stranded DNA—one of the hallmark indicators of certain types of autoimmune disease is the expression of antinuclear antibodies), red blood cells, lymphocytes, neutrophils, platelets, Igs (primarily IgG), striated muscle (cholinergic receptors), smooth muscle, mitochondria, skin (basement membranes), thyroid (thyroglobulin), kidney (glomerular and tubular basement membrane), CNS (myelin), connective tissue (synovial lining of joints), lung, and liver. Both humoral immunity and CMI can be involved as effector mechanisms in causing the damage in autoimmune conditions. Examples of autoimmune diseases include (1) myasthenia gravis, in which cholinergic receptors, especially those associated with neuromuscular junctions, are targeted; (2) multiple sclerosis, in which myelin is targeted; and (3) rheumatoid arthritis, in which connective tissue, especially the synovial lining of joints, is targeted. The terms “hypersensitivity” and “autoimmunity” are often confused and are certainly interrelated. Based on their definitions, a hypersensitivity response can be a mechanism by which an autoimmune disease is produced.

In the section on hypersensitivity presented above, two mechanisms by which host tissues are damaged by the host’s own immune system were discussed (Types II and III), creating autoimmune-like disease. In these situations, unaltered self-antigens are not the target of the immune mechanisms, but damage occurs to cells bearing hapten on membranes or to innocent bystander cells in close proximity to antigen–antibody complexes. For example, damage produced in autoimmune Goodpasture’s disease is similar to that seen in Type III hypersensitivity reactions in the lung due to trimellitic anhydride (TMA) exposure. Although the resulting pathology may be the same for autoimmune reactions and hypersensitivity, mechanisms of true autoimmune disease are distinguished from hypersensitivity. In cases of autoimmunity, self-antigens are the target, and in the case of chemical-induced autoimmunity, the disease state is induced by a modification of host tissues or immune cells by the chemical and not the chemical acting as an antigen/hapten as in hypersensitivity reactions.

Mechanisms of Autoimmunity As discussed earlier, the rearrangement and recombination of the genes that comprise Ig and TCR result in tremendous diversity in the potential antigen recognition of B cells and T cells, respectively. Ideally, during development those lymphocytes recognizing self-antigens will largely be deleted by negative selection as central tolerance is established. Autoreactive clones that escape central tolerance and migrate to the periphery are normally controlled by peripheral tolerance mediated by various mechanisms that ultimately induce anergy or clonal deletion. For autoimmune disease to occur, an autoreactive clone must escape central tolerance, pass into the periphery, and bind with specificity to its self-antigen then mechanisms of peripheral tolerance must fail and the autoreactive clone must induce a detrimental immunological response. Clearly, induction of autoimmunity is multifaceted and likewise has been associated with several mechanisms primarily related to insufficient peripheral tolerance. Conversely, defects in central tolerance are rarely encountered. However, an example of autoimmunity due to defective central tolerance is the disease autoimmune polyendocrinopathy candidiasis ectodermal dystrophy, which results from a defective transcriptional regulator called autoimmune regulator (AIRE). For the negative selection process in the thymus, AIRE induces the

expression of a wide variety of self-antigens normally found in the periphery. Loss of AIRE results in release of autoreactive T cells to the periphery. Several mechanisms have been associated with the breakdown of peripheral tolerance and prime events for the onset of autoimmune disease. These mechanisms include inflammation; molecular mimicry by pathogen antigens; inherent defects in T or B cells including regulatory subsets, APCs, cytokines, or complement; and epitope spreading. For example, increasing evidence supports a potential breakdown of peripheral tolerance during an inflammatory response, which may be mediated by the inappropriate maturation of immature DCs that process both pathogenic antigens and self-antigens released during the inflammatory response. Self-antigens could then be presented to naive autoreactive T cells via MHC. With molecular mimicry, a pathogen presents epitopes that resemble those on self-antigens and because the pathogen will induce a strong inflammatory response, peripheral tolerance may be overridden. Defects in immune system components, such as complement, could reduce C3b-mediated clearance of self-antigen and autoantibody immune complexes (described in Types II and III hypersensitivity). Additionally, interference of normal immune regulation by Tregs or Bregs could create an environment conducive to autoimmune disease. Finally, epitope spreading may occur during an immune response due to tissue damage and the release of new epitopes that were hidden either because they were sequestered from the immune system or their expression levels were insufficient to induce negative selection or peripheral tolerance mechanisms.

Effector mechanisms involved in autoimmune disease can be the same as those described earlier for Types II and III hypersensitivity or, in the case of pathology associated with solid tissues, including organs, they may involve CD8⁺ CTL. Tissue damage associated with CTL may be the result of direct cell membrane damage and lysis, or the result of cytokines produced and released by the T cell. TNF- β has the ability to kill susceptible cells, and IFN- γ may increase the expression of MHCI on cell surfaces, making them more susceptible to CD8⁺ cells. Cytokines may also be chemotactic for macrophages, which can cause tissue damage directly or indirectly through the release of proinflammatory cytokines. As is the case with hypersensitivity reactions, autoimmune disease is often the result of more than one mechanism working simultaneously. Therefore, pathology may be the result of direct or indirect effects of CTL, antibody-dependent cytotoxicity, or complement-dependent antibody-mediated lysis.

Developmental Immunology

A sequential series of carefully timed and coordinated developmental events, beginning early in embryonic/fetal life and continuing through the early postnatal period, is required to establish a functional immune system in all mammals, including humans. The immune system develops initially from a population of pluripotent HSCs that are generated early in gestation from uncommitted mesenchymal stem cells in the intraembryonic splanchnopleure surrounding the heart. This early population of HSCs gives rise to all circulating blood cell lineages, including cells of the immune system, via migration through an orderly series of tissues, and a dynamic process that involves continual differentiation of lineage-restricted stem cells. Lymphoid-hematopoietic progenitor cells are established via the migration of these cells from intraembryonic mesenchyme to fetal liver and fetal spleen, and ultimately, the relocation of these cells in late gestation to bone marrow and thymus. The latter two organs are the primary sites of lymphopoiesis and appear to be unique in providing the microenvironment factors

necessary for the development of functionally competent immune cells. These lineage-restricted stem cells expand to form a pool of highly proliferative progenitor cells that are capable of continual renewal of short-lived functional immunocompetent cells, and that ultimately provide the necessary cellular capacity for effective immune responsiveness, and the necessary breadth of the immune repertoire (Good, 1995).

It is important to recognize that immune system development does not cease at birth, and that immunocompetent cells continue to be produced from proliferating progenitor cells in the bone marrow and thymus. Mature immunocompetent cells leave these primary immune organs and migrate via the blood to the secondary immune organs: spleen, lymph nodes, and mucosal lymphoid tissues. Because birth occurs at various stages of fetal maturity, the significance of parturition as a landmark in the development of the immune system can vary from species to species (Holsapple *et al.*, 2003). As such, direct comparison of immune functional development between humans and animals is complicated by differences in the maturity of the immune system before and after parturition. This difference has been linked to the length of gestation (Holladay and Smialowicz, 2000) in that animals with short gestation periods (eg, mice, rats, rabbits, and hamsters) have relatively immature immune systems at birth compared to humans. The onset of functional immune competence depends on the specific parameter being measured, and varies across species with striking differences noted between rodents and humans (Holsapple *et al.*, 2003). The consensus in the scientific and regulatory arenas is that the immune system of children continues to develop postnatally until 5 to 12 years of age (Miyawaki *et al.*, 1981). Exposure to specific antigens during the perinatal period results in a rapidly expanding accumulation of lymphocyte specificities in the pool of memory cells in secondary lymphoid tissues. As thymic function wanes and thymocytes are no longer produced in that tissue, it is this pool of memory B and T cells that maintains immune competence for the life of the individual. Senescence of immunity is associated with reductions in both innate and acquired immune responses to antigens during the last quartile of life. This failure of the immune response is due, in part, to a continual reduction in the production of newly formed cells, and to the decreased survival of long-lived memory cells in lymphoid tissues. The concept of immune senescence is discussed further below.

One feature of the developing immune system that clearly distinguishes it from the mature immune system, especially during gestation, is the role played by organogenesis. Defects in the development of the immune system due to heritable changes in the lymphoid elements have provided clinical and experimental examples of the devastating consequences of impaired immune development (Rosen *et al.*, 1995). Therefore, the effects of chemicals on the genesis of critical immune organs in the developing fetus may be more important than effects on these tissues after having been populated by hematopoietic and lymphoid cells. However, a chemical that induces this kind of developmental structural abnormality in the fetus would legitimately be classified as a teratogen, prompting the question as to how many known teratogens would have an impact on organs essential to the normal functioning of the immune system. Interestingly, immune organs, such as the thymus, spleen, and/or bone marrow, are not typically assessed in routine developmental and reproductive toxicology studies, and it has been noted that this failure to assess developmental damage to the immune system in standard developmental and reproductive toxicology protocols should be reevaluated (Holsapple *et al.*, 2003). Additional perspectives on the methods to assess developmental immunotoxicology (DIT) and on the emergence of regulatory guidelines that include

developmental immunotoxicity testing strategies are included elsewhere in this chapter.

At the other end of the spectrum from the development of the immune system during gestation and the perinatal period is the status of the immune system in the aging population. Unlike DIT, there have been very few studies that have addressed the impact of specific xenobiotics on the aging immune system. Nonetheless, it is known that the immune system of older people is usually perceived as declining in fidelity and efficiency with age resulting in an increased susceptibility to infectious diseases and pathological conditions relating to inflammation (eg, cardiovascular disease and Alzheimer's disease) or autoreactivity (eg, rheumatoid arthritis) (Caruso *et al.*, 2009). Immune senescence has been defined as the impairment in immunity as a result of age-associated changes in function in a variety of cell types. It is a phenomenon of decreased function, involving changes in both innate and adaptive immunity, and a disbalance between the two arms (Pawelec *et al.*, 2010). Virtually, all components of the immune system are affected (Ongradi and Kovessi, 2010). The decline in the B-cell compartment is responsible for the decreased effectiveness of vaccines in older people; and the decline in immune surveillance (eg, the T-cell compartment and NK-cell function) is associated with an increased incidence in malignancy. Additionally, aging has been associated with a shift from the Th1 to the Th2 cytokine profile in response to immune stimulation, and the overproduction of Th2 cytokines could augment B-cell production of autoreactive antibodies. Studies in humans and mice have shown that TLR expression and function decline with age resulting in the decreased production of proinflammatory cytokines and chemokines. From a mechanistic standpoint, a number of factors have been proposed as contributing to the onset and severity of immune senescence including: the accumulation of damage to lymphocytes by oxidative stress, persistent microbial infections with immunosuppressive viruses that establish latency, such as cytomegalovirus and Epstein-Barr virus, and lifestyle factors such as smoking, alcohol use, and poor nutrition. An improved understanding of immune dysfunction in human aging will increase the probability of discovering means to restore appropriate function and alleviate the burden of infectious disease later in life (Ongradi and Kovessi, 2010).

Neuroendocrine Immunology

There is overwhelming evidence that cytokines, neuropeptides, neurotransmitters, and hormones, as well as their receptors, are an integral and interregulated part of the CNS, the endocrine system, and the immune system (reviewed by Sanders and Kohm, 2002). Because receptors for neuropeptides, neurotransmitters, and hormones are present on lymphoid cells, it is reasonable to suspect that some chemicals may exert their immunomodulatory effects indirectly on the immune system by acting to modulate the activity of the nervous or endocrine systems. In addition, immune cells are capable of secreting, and do secrete, peptide hormones and neurotransmitters, which can have autocrine (immune system) and paracrine (endocrine and nervous systems) effects. Similar to the complexity of the cytokine network, the effects of various hormones and neurotransmitters are too vast to discuss here. However, it is evident, even from this brief overview of the immune system and its potential interaction with other biological systems, that immune responses are complex processes involving multiple cell types and mediators. It is not difficult to imagine then, that perturbation of leukocyte functions including the mediators they produce by drugs or chemicals could contribute to the mechanisms by which a compound is immunotoxic.

ASSESSMENT OF IMMUNOLOGICAL INTEGRITY

For many years, it has been widely established that xenobiotics can exert significant effects on the immune system as evidenced by changes in circulating and lymphoid organ-associated leukocyte number, proliferative capacity, and in effector functions including defense against a broad array of bacterial, parasitic, and viral pathogens. More recently, and during the establishment of the sub-discipline of immunotoxicology, a significant emphasis was placed on the development of a standardized battery of tests to evaluate immune competence. Among the unique features of the immune system is the ability of immune cells to be removed from the body and to function *in vitro*. This unique quality makes it possible to comprehensively evaluate the actions of xenobiotics on the immune system employing *in vivo*, *ex vivo*, and *in vitro* approaches to dissect the cellular, biochemical, and molecular mechanisms of action of xenobiotics. While standard toxicological endpoints such as organ weights, cellularity, and enumeration of cell populations are important components in assessing when an agent is capable of altering the immune system, by far the most sensitive indicators of immunotoxicity are the tests that challenge the various cell types within the immune system to respond functionally to exogenous stimuli (Descotes, 2004; White, 1992). Employing such a battery of functional assays whereby different cell types can be evaluated not only for their effector functions, but also in certain cases for their ability to participate as accessory cells in an immune response, can provide important mechanistic information concerning which cell type(s) within the immune system are, in fact, targeted by a xenobiotic. This section focuses on selected *in vivo*, *ex vivo*, and *in vitro* tests currently used for evaluating immunotoxicity, as well as models and approaches that can be utilized for elucidation of the mechanism of action.

Methods to Assess Immunocompetence

The current state-of-the-science of immunotoxicity testing was recently reviewed in a single volume of *Methods in Molecular Biology*. An overview of immunotoxicology testing: past and future was provided by Luster and Gerberick (2010).

General Assessment Central to any series of studies evaluating immune competence is the inclusion of standard toxicological studies, because any immunological finding should be interpreted in conjunction with effects observed on other target organs. Standard toxicological studies that are usually evaluated include body and selected organ weights, general observations of overall animal health, selected serum chemistries, hematological parameters, and status of the bone marrow (ability to generate specific colony-forming units). In addition, histopathology of lymphoid organs, such as the spleen, thymus, and lymph nodes, may provide insight into potential immunotoxicants. General guidelines for the histopathological examination of each of these lymphoid organs was recently reviewed (Elmore, 2010).

Because of the unique nature of the immune system, there are several experimental approaches that may be taken to assess immunotoxicity and to evaluate the mechanisms of action of xenobiotics. These are depicted in Fig. 12-19 and vary with respect to *in vivo* or *in vitro* exposure, immunological challenge (ie, the stimulus employed to induce an immune response), or immunological evaluation (immune assay). As an example, Fig. 12-19 (2) is an *ex vivo* assay where xenobiotic exposure and antigen challenge occur *in vivo* and the immune response is evaluated *in vitro*. In contrast, as depicted in Fig. 12-19 (3), splenocytes can be isolated after *in vivo*

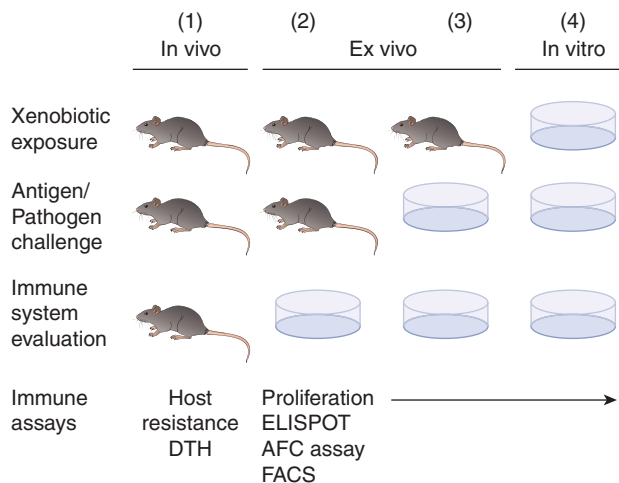

Figure 12-19. Approaches for assessing the immunotoxicity of xenobiotics. The ability to stimulate immune cells *in vitro* allows for much flexibility in the assessment of immunotoxicity of xenobiotics.

treatment with a xenobiotic, sensitized with an antigen *in vitro* and evaluated *in vitro*; or as depicted in Fig. 12-19 (4), splenocytes can be removed from a naive (untreated) animal, exposed to a xenobiotic and antigen *in vitro*, and evaluated *in vitro*. If splenocytes are sensitized *in vitro* with sRBC to generate AFC, this is known as the Mishell–Dutton assay (Mishell and Dutton, 1967).

Functional Assessment

Innate Immunity As described earlier, innate immunity encompasses all those immunological responses that are not induced through antigen receptors (ie, TCR or BCR) and for which there is no immunological memory. These responses include recognition of tumor cells by NK cells, phagocytosis of pathogens by macrophages, and the lytic activity of the components of the complement cascade.

To evaluate phagocytic activity, phagocytic cells, typically macrophages are harvested from the peritoneal cavity (peritoneal exudate cells) and are allowed to adhere either in a well of a tissue culture plate or in a chamber fabricated on a tissue culture slide. After adherence, macrophages are washed and incubated with fluorescently labeled latex covaspheres. At the end of incubation, cells are fixed in methanol and stained in methylene chloride. Macrophages containing five covaspheres or more are counted as positive for phagocytic activity and data are expressed as a percentage of phagocytosis (the ratio of macrophages with ≥ 5 covaspheres to total macrophages counted).

Phagocytosis assays are conducted *in vitro* after chemical exposure either *in vivo* or *in vitro*. If an *in vivo* assay to assess the ability of tissue macrophages to phagocytose a foreign antigen is required, the functional activity of the reticuloendothelial system can be evaluated. Intravenously injected radiolabeled sRBC (^{51}Cr -sRBCs) are removed from the circulation by the tissue macrophage and sequestered for degradation in organs such as the liver, spleen, lymph nodes, lung, and thymus. Clearance of the ^{51}Cr -sRBCs is monitored by sampling of the peripheral blood. When steady state has been attained, animals are euthanized and organs are removed and counted in a gamma counter to assess uptake of the ^{51}Cr -sRBCs.

When phagocytic cells encounter antigens, especially those associated with bacteria or a virus, they undergo activation, which is induced, in part, through interactions with TLRs. Extracellular antigens are processed and presented in association with MHCII, while intracellular antigens are processed and presented in association

with MHCI, as described in the “Antigen Processing” section. Concomitantly with antigen encounter by the phagocyte, there is an increase in the expression of MHCI and/or MHCII as well as the costimulatory molecules CD80/CD86. The simultaneous increase in MHC molecules in combination with CD80 and CD86 is critically important in order for the phagocytic cell to drive T-cell effectors (CD4⁺ and CD8⁺ T cells). The upregulation of MHCI and/or II and CD80 and CD86 can be readily quantified by flow cytometry (see the “Flow Cytometric Analysis” section) after the activation of phagocytic cells, primarily those of the monocytic lineage, to further assess phagocytic cell function and the influence of an immunotoxicant. These measurements are especially informative when performed in combination with cell surface markers that are capable of identifying monocytic lineage subpopulations, for example such as tissue macrophages, conventional DC, and plasmacytoid DC because they provide information on whether the immunotoxicant interferes with the activation/differentiation of the phagocytic cell and its antigen-presenting capability. An overview of the types of macrophages, their hematopoietic origin, and a general discussion of the many different assays that are used to assess their functional status was recently provided by Barnett and Brundage (2010).

Evaluation of the ability of NK cells to lyse tumor cells is achieved using the YAC-1 cell line as a tumor target for an in vitro cytotoxicity assay. YAC-1 cells are radiolabeled with ⁵¹Cr and incubated (in microtiter plates) in specific effector-to-target ratios with splenocytes from xenobiotic-exposed and nonexposed animals. During an incubation step, splenic NK cells (effectors) lyse the ⁵¹Cr-YAC-1 cells, releasing ⁵¹Cr into the supernatant. At the end of the incubation, plates are centrifuged and the supernatant is removed and counted on a gamma counter. After correcting for spontaneous release (which should be <10%), specific release of ⁵¹Cr is calculated for each effector-to-target ratio and compared to the specific release from control animals. To avoid the use of radionucleotides, a number of flow cytometry based assays have been developed utilizing fluorescent stains to identify live and dead target cells. One such assay involves the coculture of NK cells with target cells that have been stained with the fluorescent green dye 3,3'-diiodoacetylcarboxycyanine perchlorate (DiO) (Kane *et al.*, 1996). Utilizing DiO allows for readily discriminating between target and nontarget cells while propidium iodide is used to distinguish between live and dead cells. The various methods for NK assays used in immunotoxicity testing were recently reviewed (Li, 2010).

Acquired Immunity—Humoral The AFC assay is a sensitive indicator of immunological integrity for several reasons. It is a test of the ability of the host to mount an antibody response to a specific antigen. When a T-dependent antigen (an antigen that requires T cells to help B cells make antibody) like sRBC is used, this response requires the coordinated interaction of several different immune cells: APC (macrophages and DCs), T cells, and B cells. Therefore, an effect on any of these cell types (eg, antigen processing and presentation, cytokine production, proliferation, or differentiation) can have a profound impact on the ability of B cells to produce antigen-specific antibody. Other antigens, termed T-cell-independent antigens, such as dinitrophenyl-ficoll or trinitrophenyl-LPS, can also be used that bypass the requirement for T cells in eliciting antibody production by B cells. Although the AFC response assay was developed almost half a century ago, its sensitivity in identifying immunotoxicants has resulted in worldwide application for the purpose of hazard identification, which extends to present day (see the “Historical Perspective on Regulatory Guidance in Immunotoxicology” section).

A standard AFC assay involves immunizing control and xenobiotic-exposed mice either intravenously or intraperitoneally with sRBCs. The antigen is taken up in the spleen, and an anti-sRBC antibody response is induced. In the mouse, the peak day of antibody production is four days after immunization. Historically, the antibody response has been quantified by enumerating the number of plasma cells present in the spleen that are secreting anti-sRBC antibodies. This can be accomplished by removing the spleen, making a spleen cell suspension that is then mixed with sRBC, complement, and melted agar. This mixture is poured onto a petri dish and covered with a cover slip. After the agar hardens the petri dishes are incubated for three hours at 37°C. During this time, the B cells that have been appropriately activated by the antigen and have differentiated into plasma cells secrete anti-sRBC IgM antibody. When the complement and the secreted IgM coat the surrounding sRBCs, areas of hemolysis (plaques) appear against a lawn of sRBC that can be enumerated. At the center of each plaque is a single B cell (AFC). Data are usually presented as IgM AFC per million splenocytes. IgG AFC can also be enumerated by slight modifications of this same assay. This isotype switching (from IgM to IgG) is important in secondary responses in which memory B cells respond more quickly to an antigen. An overview of the T-cell-dependent antibody response to sRBCs was recently provided, in which this model is described as the “gold standard” for evaluating the potential adverse effects of xenobiotics on the immune system (White *et al.*, 2010).

A second method to enumerate AFC cells is by ELISPOT. This method is similar to the plaque assay described above with the exception that the splenocytes isolated from sRBC-sensitized mice are incubated on ELISPOT microtiter plates coated with either antimouse IgM or sRBC membranes to capture the secreted IgM. After incubation, the spleen cells are removed using a washing buffer followed by incubation with an enzyme-conjugated antimouse IgM antibody. A second washing step is used to remove unbound enzyme-conjugated antimouse IgM followed by addition of the chromogen substrate. The site at which each IgM secreting cell was present in the well of the ELISPOT microtiter plate is now visualized by the formation of a “spot” through the enzymatic conversion of the chromogen substrate. Typically, enumeration is performed using an ELISPOT reader that can rapidly quantify spot number (number of plasma cells) as well as the size and intensity (quantity of IgM being secreted) of the spots. It is noteworthy that in addition to enumeration of AFCs, the ELISPOT method can be applied to quantification of any secreted protein for which a suitable capture antibody exists. In evaluations of immunocompetent cells, the ELISPOT is especially useful for enumerating cytokine and chemokine secreting cells, and serves as an alternative to flow cytometry, where cell enumeration is critical.

A third way the anti-sRBC humoral immune response can be evaluated is ex vivo using serum from peripheral blood of immunized mice and an enzyme-linked immunosorbent assay or ELISA. Although the optimal response is delayed by one to two days (compared to the AFC assay), this approach takes into account antigen-specific antibody secreted by B cells in the spleen as well as B cells residing in the bone marrow. Like the AFC assay, mice (or other experimental animals) are immunized with sRBCs and six days postimmunization peripheral blood is collected. Serum from each sample is serially diluted and incubated in microtiter plates that have been coated with sRBC membranes. The membranes serve as the antigen to which sRBC-specific IgM or IgG will bind, as described above in the ELISPOT assay. After incubation of the test sera and a wash step, an enzyme-conjugated monoclonal antibody (the secondary antibody) against IgM (or IgG) is added. This antibody recognizes the IgM (or IgG) and binds specifically to that

antibody. After incubation and a wash step, the enzyme substrate (chromogen) is added. Conversion of the substrate by the enzyme conjugated to the secondary antibody results in a color change, which can be quantified by measuring absorbance with a plate reader. Because this is a kinetic assay (color develops over time and is dependent on concentration of anti-sRBC antibody in the test sera), it is important to establish control concentration–response curves so that data can be evaluated in the linear range of the curve. Data are usually expressed in arbitrary optical density (OD) units. An advantage of the ELISA over the AFC assay and ELISPOT is the ability to attain a greater degree of flexibility, since serum samples can be stored frozen for analysis at a later date. In contrast, a disadvantage of the ELISA approach is that it provides no information on the actual number of plasma cells that were induced by sRBC sensitization. Other T-dependent antigens, including keyhole limpet hemocyanin (KLH), are routinely used to drive an antigen-specific antibody response and to assess the potential for immunotoxicity (Plitnick and Herzyk, 2010).

B cell to plasma cell differentiation can also be monitored by flow cytometry. This can be accomplished utilizing intracellular staining for IgM (or other Ig isotypes such as IgG) to identify IgM^{high} cells in combination with the transmembrane proteoglycan, CD138, also termed syndecan-1, which is a hallmark of a fully differentiated plasma cell (Costes *et al.*, 1999). It is noteworthy that even in resting nonactivated B cells, background levels of intracellular IgM are readily detectable because the monomeric form of IgM serves as the B-cell antigen receptor. For this reason, the designation IgM^{low} typically refers to a resting B cell versus IgM^{high}, which is indicative of high level IgM expression as exhibited by plasma cells.

One final assay measures the ability of B cells to undergo blastogenesis and proliferation, which are critical steps in the generation of an antibody response. Lymphocyte proliferation is most often quantified either using a radioisotope-based assay or by flow cytometry. Splenocytes are stimulated in microtiter plates with a monoclonal antibody to surface Ig in the presence of IL-4, or with a B-cell mitogen such as LPS. Proliferation is evaluated two to three days after stimulation. In the radioisotope-based assay, proliferation is quantified by quantifying the incorporation of ³H-thymidine into the DNA of the cultured cells. Data are usually expressed as mean counts per minute (cpm) for each treatment group. In the flow cytometry-based assay, cells are stained with one of several membrane permeable dyes such as carboxyfluorescein succinimidyl ester (CFSE). CFSE is a colorless dye that passively diffuses into the cell. Once inside the cell, CFSE undergoes cleavage by intracellular esterases to yield carboxyfluorescein succinimidyl, which is highly fluorescent and covalently reacts with intracellular amines. As the cell divides, the intensity of staining in each of the two newly formed daughter cells decreases by approximately half, as well as in every subsequent cell division thereafter. The number of cell divisions each cell has undergone is inversely proportional to fluorescence intensity. T-cell proliferative responses can be quantified using the same methodologies as described above with the exception that T-cell-specific stimuli are used to induce T-cell proliferation. Often in broad-based immunotoxicological evaluations, B-cell proliferative responses are measured in conjunction with T-cell proliferation.

Acquired Immunity—Cell-Mediated While there are numerous assays used to assess CMI, three primary tests are used routinely in the National Toxicology Program (NTP, 2009) test battery (see the “The National Toxicology Program Tier Approach” section later in this chapter). The test battery includes the CTL assay, DTH response, and the T-cell proliferative responses to antigens

(anti-CD3 + IL-2), mitogens (phytohemagglutinin [PHA] and concanavalin A [Con A]), and allogeneic cell antigens (mixed lymphocyte responses [MLR]).

The CTL assay measures the *in vitro* ability of splenic T cells to recognize allogeneic target cells (MHC mismatched) by evaluating the ability of the CTLs to proliferate and then lyse the target cells. Splenocytes are incubated with P815 mastocytoma cells, which serve as target cells. The target cells are pretreated with mitomycin C or irradiated, so that they cannot proliferate. During this sensitization phase, the CTLs recognize the targets and undergo proliferation. Five days after sensitization, the CTLs are harvested and incubated in microtiter plates with radiolabeled (⁵¹Cr) P815 mastocytoma cells. During this elicitation phase, the CTLs that have acquired memory recognize the foreign MHC I on the P815 cells and lyse the targets. At the end of the incubation, the culture plates are centrifuged, the supernatant is removed, and radioactivity released into the supernatant is quantified on a gamma counter. After correcting for spontaneous release, the percent cytotoxicity is calculated for each effector-to-target ratio and compared to that from control animals. Several flow cytometry-based methods have also been developed to assay CTL activity that avoids the use of radionucleotides. One approach is similar to the one described for the NK cell assay above and involves the labeling of target cells with a fluorescent dye (eg, DiO or CFSE) in order to discern target cells from effectors. After coculture of target cells and CTL effectors, target cell viability is assessed by propidium iodide staining or using one of several other commercially available stains to assess viability. Another alternative nonradioactive surrogate assay widely used in place of measuring direct killing of target cells is quantification of IFN γ expressing CD8⁺ T cells by flow cytometry using intracellular staining. An inherent limitation to this last approach is that direct target cell killing is not assessed and it is assumed that all IFN γ CD8⁺ cells identified are CTL effectors (see the “Flow Cytometric Analysis” section). The current state-of-the-science of using the CTL assay to evaluate the effects of xenobiotics on CMI function was recently provided by Burleson *et al.* (2010).

The DTH response evaluates the ability of memory T cells to recognize foreign antigen, proliferate and migrate to the site of the antigen, and secrete cytokines and chemokines, which result in the influx of other inflammatory cells. The assay itself quantifies the influx of radiolabeled mononuclear cells into the sensitization site. During xenobiotic exposure, mice are sensitized twice with KLH subcutaneously between the shoulders. On the last day of exposure, mononuclear cells are labeled *in vivo* with an IV injection of ¹²⁵I-5-iododeoxyuridine. One day later, mice are challenged intradermally in one ear with KLH. Twenty-four hours after challenge, animals are euthanized, the ears are biopsied, and radiolabeled cells are counted in a gamma counter. Data are expressed as a stimulation index, which represents the cpm of ¹²⁵I activity in the challenged ear divided by the cpm in the unchallenged ear. As such, the DTH functional response may be influenced by disruption of either Th1-driven, antigen-dependent T-cell development or mobilization of sensitized T cells to a local site (Dietert *et al.*, 2010).

T cells play a central role in CMI and the ability of T cells to undergo blastogenesis and proliferation is critical to this role. Several mechanisms exist to evaluate proliferative capacity. The MLR measures the ability of T cells to recognize foreign MHC I and MHC II on splenocytes from an MHC-incompatible mouse (allogeneic cells) and undergo proliferation. For example, splenocytes from B6C3F1 mice (responders) are incubated with splenocytes from mitomycin C-treated (or irradiated) DBA/2 mice (stimulators). Proliferation is evaluated four to five days after stimulation by measuring uptake of ³H-thymidine into the DNA of the cultured

responder cells. Cells are collected from each well using a cell harvester and counted in a scintillation counter. Data may be expressed as either the mean cpm for each treatment group or as a stimulation index in which the index is calculated by dividing the cpm of wells containing responders and stimulators by the cpm of wells containing responders alone. Alternatively, cell proliferation can be quantified by flow cytometry using membrane permeable dyes such as CFSE (please see the following section “Flow Cytometric Analysis”).

General T-cell proliferation can be evaluated in a manner similar to that described above for B cells (Table 12-5). Splenocytes are stimulated in microtiter plates with monoclonal antibodies directed to the CD3 complex of the TCR (anti-CD3) and the CD28 T-cell coreceptor (anti-CD28), or with the T-cell mitogens Con A or PHA. Proliferation is evaluated two to three days after stimulation by measuring uptake of ^3H -thymidine into the DNA of the cultured T cells. Data are usually expressed as mean cpm for each treatment group. As discussed above, proliferation can also be quantified by flow cytometry. These studies are usually done in conjunction with B-cell proliferative responses described above.

Flow Cytometric Analysis One of the most rapidly advancing areas and powerful tools in immunotoxicology has been the application of flow cytometry to investigations of immune modulation by xenobiotics. In the most general sense, flow cytometry is a method that employs light scatter, fluorescence, and absorbance measurements to analyze large numbers of cells (typically 5000-100,000/sample), on an individual basis. Most commonly, fluorochrome-conjugated monoclonal antibodies raised against a specific protein of interest are employed for detection. The strength of the approach is that a wide variety of measurements can be made on large numbers of cells, individually, rapidly, and with a high level of precision. In addition, methods are also available that allow for the analysis of specific proteins in cell-free preparations such as cell lysates, biological fluids, and culture supernatants. A broad selection of polyclonal and monoclonal antibodies is available to

cell surface markers, intracellular proteins, and secreted proteins (Table 12-5).

The most common application of flow cytometry in immunotoxicology is to enumerate specific leukocyte populations and subpopulations. For example, antibodies are available to the T-cell surface proteins CD4, CD8, and CD3 (among others). Because flow cytometers can detect light emission of multiple wavelengths simultaneously, multiple-colored fluorochromes can be used concurrently facilitating an analysis of more than one protein simultaneously in a given sample (multicolor/parameter analysis). In this manner, the number of CD4⁺ and CD8⁺ cells can be determined simultaneously on a single sample of cells. In the thymus, dual staining can be used to assess T-cell maturation by determining the number of CD4⁺/CD8⁺ (double positive), CD4⁻/CD8⁻ (double negative), CD4⁺/CD8⁻ (single positive), and CD4⁻/CD8⁺ (single positive) cells residing in this organ (Fig. 12-20). This approach can be used to provide insight into which specific T-cell subsets are targeted after exposure to a xenobiotic and to identify putative effects on T-cell maturation. Similarly, antibodies are readily available to identify other leukocyte subpopulations including antibodies to surface Ig, CD19, and B220 (the CD45 phosphatase on B cells) for enumerating B cells, to Mac1 and F4/80 for macrophages, to CD16/CD56 for NK cells in humans, and to CD161 (NK-1.1) for NK cells in mice. Surface marker analysis of heterogeneous cell preparations can reveal significant alterations in lymphoid subpopulations, and in many instances, this is indicative of alterations in immunological integrity. Indeed, an indicator of disease progression in AIDS can be monitored by changes in CD4⁺ T cell numbers. Luster and coworkers (1992) have reported that in conjunction with two or three functional tests, the enumeration of lymphocyte subsets can greatly enhance the detection of immunotoxic chemicals. However, it is important to emphasize that although surface marker analysis can identify changes in leukocyte populations, functional analysis of the immune system is more definitive for the detection of immunotoxicity since the ability of immunocompetent cells to mount an effector response is assessed directly.

Figure 12-20. Fluorescently activated cell sorting (FACS). As an example, a mixed lymphocyte population expressing CD4⁺ and CD8⁺ (thymocytes) is assessed. Using antibodies directed against either CD4 or CD8 conjugated to different fluorophores (“colors”), the number of cells expressing CD4, CD8, both, or none can be quantified. In addition, differential gating can be used to quantify subpopulations of cells (bottom, the number of green positive and green negative within orange negative population).

With technical advancements of flow cytometers (ie, an increased number of wavelengths that can be simultaneously detected, enhanced sensitivity of detection, and more rapid analysis) coupled with a steady growth of applications, reagents, and methods, flow cytometry has become an integral tool in elucidating the cellular and molecular mechanisms of action produced by immunotoxicants by measuring their effects on a wide variety of cellular responses. Current applications go well beyond strictly evaluating cell surface markers and include measurements of cellular viability, cell cycle, cell proliferation, intracellular free calcium, induction of apoptosis, DNA strand breaks (TUNEL assay), intracellular proteins (cytosolic and nuclear), membrane potential, intracellular pH, oxidative stress, and membrane lipophilicity (reviewed by Burchiel *et al.*, 1997, 1999; Hawley and Hawley 2004; Shapiro, 2003). Of particular utility in assessments of immune cell signaling and effector function has been the development of protocols and antibodies for intracellular staining of permeabilized cells. In the case of effector function, flow cytometry can be used to quantify the expression of multiple cytokines and/or chemokines simultaneously in individual cells by intracellular staining. Because activated leukocytes often secrete multiple regulatory factors simultaneously, termed “multifunctional,” using intracellular staining in conjunction with extracellular staining for phenotypic markers to identify specific cell populations can provide important insights into the magnitude and profile of effects exerted by an immunotoxicant on specific cell types and populations. Measurements of regulatory factors in combination with phenotypic markers can be extended to also include markers of cell activation or differentiation to identify at which stage during effector cell generation an immunotoxicant is acting. For an example of intracellular cytokine staining, refer to the study of Karmaus *et al.* (2011). A second application of intracellular staining in flow cytometry has been for investigating cell signaling. The complex networks and pathways that control cellular activities can be studied on an individual cell basis to provide static or kinetic information in specific cell types. For example, by using intracellular staining, the abundance of specific signaling proteins, cytosolic and nuclear, can be quantified. In addition to signaling protein abundance, post-translational modifications of proteins represent an important mechanism for transducing regulatory signals. One of the most extensively studied is protein phosphorylation and dephosphorylation, which often results in the activation or inactivation of protein function. The development of antibodies capable of distinguishing the point at which proteins possess phospho-groups at specific regulatory sites has made it possible to study modulation of distinct regulatory pathways by immunotoxicants. Because basic flow cytometers have the ability to detect six to eight colors simultaneously, with more advanced instruments possessing 18 color capacity, it is possible to measure multiple signaling events and/or network interactions in single cells. This capability coupled with the fact that the flow cytometer can evaluate thousands of cells per second, allows for accurate and reproducible detection of even rare events occurring in small subsets of leukocytes. Moreover, flow cytometry has numerous advantages over other approaches such as Western blotting and immunoprecipitation because of the rapidity of analysis and that it is not a “bulk lysis” method in which all cells in a given sample are pooled for analysis to render results that are representative of the overall mean within the entire cell population rather than in individual cells. For examples of measurement of intracellular phosphoprotein and transcription factors by flow cytometry that can be applied to study mechanisms of immune modulation, see North *et al.* (2010) and Lu *et al.* (2011).

Another major advancement in flow cytometry-based analyses has been the development of fluorescent microspheres that are

individually identified by the instrument. By coating the surface of microspheres with various concentrations of two fluorescent dyes, sets of microspheres can be generated with each set possessing a unique spectral signature. Subsequently, various materials (ie, proteins, antibodies, or nucleic acids) can be covalently conjugated to the surface of these microspheres in order to create unique detection systems. This technology is being widely applied for analyzing a broad variety of soluble cellular components including proteins in cell-free preparations by flow cytometry. For example, up to 15 different cytokines can be measured simultaneously in cell supernatants or biological fluids (eg, BALF). A major advantage of this method over more traditional approaches, such as ELISA-based assays, is that only small amounts of biological samples and reagents are required because multiple proteins are assayed simultaneously. The same technology is also being applied for analyzing cell lysates for changes in protein phosphorylation in investigations of cell signaling. In addition, flow cytometry is routinely used to purify and isolate leukocyte subpopulations from heterogeneous cellular preparations. Thus, flow cytometry has become a powerful tool for characterizing the cellular and molecular mechanisms associated with immunotoxicants.

For information concerning specific flow cytometry protocols and applications beyond those provided by commercial vendors, the reader is directed to several references including the 4th edition of *Practical Flow Cytometry* (Shapiro, 2003), the 2nd edition of *Methods in Molecular Biology: Flow Cytometry Protocols* (Hawley and Hawley, 2004), and the Purdue University Cytometry Laboratories website (www.cyto.purdue.edu), which hosts the “Discussion List,” a blog to which one can submit questions to the broader community of flow cytometry users for technical assistance.

Measurements of Cytokines and Cytokine Profiling As discussed in the earlier part of this chapter, development, maturation, differentiation, and effector responses of the immune system are highly dependent on a multitude of small, secreted proteins termed cytokines. In most cases, these immunological processes are controlled by the production of multiple cytokines, some of which are released simultaneously while others are released in a very defined temporal sequence. Many of these cytokines are produced by T cells and are the mechanism by which a wide variety of functions by T cells are mediated. Due to the importance of cytokines in regulating the immune system, xenobiotics that alter the production and release of these mediators can significantly affect immune competence. Therefore, measurement of multiple cytokines, often referred to as cytokine profiling, has become routine in immunotoxicology and can provide significant insights into the mechanisms by which a xenobiotic produces its immunotoxicity. For example, cytokine profiling has been explored as an approach for identifying chemical allergens, either contact sensitizers, which typically induce a Th1 profile of cytokines (IL-2, IFN- γ , and TNF- β), or respiratory sensitizers, which typically produce a strong Th2 cytokine profile (IL-4, IL-5, IL-6, and IL-10) (Mosmann and Coffman, 1989; Mosmann *et al.*, 1991). Cytokines can be measured in cell culture supernatants or biological fluids (ie, serum or BALF) by ELISA or by multiplex assays. Quantification of test samples is accomplished by comparison to a standard curve employing recombinant cytokine standards. The aforementioned method, the ELISPOT assay can also be used to quantify the number of cells producing the cytokine of interest. Likewise, flow cytometry can be used to identify cytokine producing cells by intracellular staining or to quantify cytokines in media or biological fluids with the main advantage being that the source of the cytokine(s) can be identified using the former approach and that many cytokines can be assayed simultaneously from one sample

using the latter approach (see the “Flow Cytometric Analysis” section). Because cytokines are regulated transcriptionally and then actively synthesized by cells at the time they are secreted, rather than existing as stored proteins, measurements of cytokine mRNA levels have become another common approach of assessing which cytokines are being expressed at a given time and the putative effects xenobiotics exert on their regulation and expression. Real time polymerase chain reaction (PCR) is most commonly used for quantifying mRNA levels of specific cytokines as well as for other genes of interest in cells or tissues. For more global assessments of mRNA levels, low-density RNA arrays or microarrays can be applied. Major advantages to quantifying cytokine expression at the mRNA rather than the protein level include significantly greater sensitivity, the ability to quantify expression in solid tissues, and the capability to rapidly design appropriate reagents (PCR primers) specific for any cytokine. A major disadvantage is that changes at the mRNA level for a given cytokine may not necessarily correlate with changes in protein. Another disadvantage over flow cytometric determinations by intracellular staining is not knowing the cell type(s) from which the cytokines are being produced. One additional limitation to cytokine measurements by ELISA or via quantification of cytokine mRNA levels is that neither of these approaches provides information concerning the biological activity of the proteins being measured. As described by Corsini and House (2010), multicytokine analysis still needs to be standardized in terms of optimum sources for analysis, protocols, and quality control issues, such as the use of reference standards and the expression of results.

Host Resistance Assays Host resistance assays represent a way of assessing how xenobiotic exposure affects the ability of the host to combat infection by a variety of pathogens. Although host resistance studies provide significant insight into the mechanisms by which an immunotoxicant is acting, these assays are not used as a first or only choice for evaluating immune competence. The results from host resistance assays are typically more variable than other immune function assays already discussed and therefore require markedly greater numbers of animals in order to obtain statistical power. The increased number of animals required also raises ethical considerations as well as cost. In addition, as with other immune function tests, no single host resistance model can predict overall immune competence of the host, primarily because each model uses different mechanisms for elimination of various pathogens. A representative list of host resistance models is shown in Table 12-7. Typically, three challenge levels of pathogen (approximating the lethal dose 20 [LD₂₀], lethal dose 50 [LD₅₀], and lethal dose 80 [LD₈₀]) for each concentration of xenobiotic are used in order to be able to detect both increases and decreases in resistance. Endpoint analyses are lethality (for bacterial and viral pathogens), changes

in tumor burden, and increased or decreased parasitemia. In host resistance studies, it is also important to consider the following: (1) strain, route of administration, and challenge size of the pathogen; (2) strain, age, and sex of the host; (3) physiological state of the host and the pathogen; and (4) time of challenge with the pathogen (prior to, during, or after xenobiotic exposure). All of these can have significant effects on the results from any individual study.

A major advantage in applying host resistance models to investigations of immunotoxicity is the ability to study the effects of an immunotoxicant within the context of the intact immune system encompassing all its diversity as it acts to protect the host against a *bona fide* pathogen. It is important to emphasize that the immune system possesses significant redundancy (ie, multiple mechanisms to provide defense against invading microorganisms). Therefore, even if a particular cell type or effector response has been compromised by exposure to an immunotoxicant, other components of the immune system might provide partial or complete protection to the host from pathogen challenge. In addition, certain pathogens are restricted to specific tissues or anatomical sites, for example influenza, which is typically restricted to airways. Using host resistance models permits the study of immunotoxicants and their effects within the environment and context of the tissue targeted by the pathogen (Buchweitz *et al.*, 2007). The current state-of-the-science of a variety of host resistance models was recently reviewed including bacterial challenge models (Burlison and Burlison, 2010), viral host resistance models (Freebern, 2010), parasite challenge models (Luebke, 2010), and tumor challenge models (Ng *et al.*, 2010).

Assessment of Developmental Immunotoxicology Interest in DIT is predicated on the recognition that the developing immune system represents a novel target for xenobiotic-induced toxicity that presents some special considerations when it comes to assessment. The concept that any of a number of dynamic changes associated with the developing immune system might provide periods of unique susceptibility to chemical perturbation has been reviewed (Dietert *et al.*, 2000; Holladay and Smialowicz, 2000). This unique susceptibility may be manifested as a qualitative difference, in the sense that a chemical could affect the developing immune system without affecting the adult immune system, or as a quantitative difference, in the sense that a chemical could affect the developing immune system at lower doses than the adult immune system, or as a temporal difference, in the sense that a chemical could produce either a more persistent effect in younger animals than adults, or trigger a delayed effect (ie, the consequences of early exposure are not manifested until early adulthood). As a result, while effective assessment of DIT should certainly draw upon the prior experience gained from adult-exposure immunotoxicity assessments, it is important to examine the database of known immune changes that reflect the potential for unique susceptibility and are specific for the developing immune system (Dietert and Piepenbrink, 2006b).

One of the most comprehensive reports to date attempted to compare the immunotoxicity following developmental or adult exposure to the following compounds: diethylstilbestrol, diazepam, lead, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), and tributyltin oxide (Luebke *et al.*, 2006a). The selection of these five compounds was reported to be based on the availability of some human data. The authors concluded that for all five chemicals, the developing immune system was found to be at greater risk than the adult, either because lower doses produced immunotoxicity, adverse effects were persistent, or both. However, it is noteworthy that no developmental immunotoxicants have been identified that have not also been immunomodulatory in the adult animal. Importantly, this observation may merely reflect the state-of-the-science—for example, all

published DIT studies to-date have been conducted on known adult immunotoxicants, and systematic studies comparing the effects across multiple developmental windows are still uncommon.

A better understanding of the developing immune system, and in particular, an understanding of critical developmental hallmarks has prompted some to speculate about the existence of five critical windows of vulnerability (Dietert *et al.*, 2000). The first window encompasses a period of HSC formation from undifferentiated mesenchymal cells. Exposure of the embryo to toxic chemicals during this period could result in failures of stem cell formation, abnormalities in production of all hematopoietic lineages, and altered immunocompetence. The second window is characterized by migration of hematopoietic cells to the fetal liver and thymus, differentiation of lineage-restricted stem cells, and expansion of progenitor cells for each leukocyte lineage. This developmental window is likely to be particularly sensitive to agents that interrupt cell migration, adhesion, and proliferation. The critical developmental events during the third window are the establishment of bone marrow as the primary hematopoietic site and the establishment of the bone marrow and the thymus as the primary lymphopoietic sites for B cells and T cells, respectively. The fourth window addresses the critical periods of immune system functional development, including the initial period of perinatal immunodeficiency, and the maturation of the immune system to adult levels of competence. The final window addresses the subsequent period during which mature immune responses are manifested, and functional pools of protective memory cells are established.

Most recently, considerable attention has been focused on the perinatal period (ie, prior to and just after birth) because this window of development is known to be replete with dynamic immune changes, many of which do not occur in adults (Dietert and Piepenbrink, 2006b). Indeed, one reality associated with DIT windows is that the developing immune system exists in an unbalanced state through the latter portion of gestation with certain functional CMI capacities deliberately impaired. In fact, Taylor and coworkers (2006) demonstrated that placentally induced immune skewing via the release of Fas-ligand-containing exosomes is one hallmark of a successful pregnancy brought to full term. Upon birth, restoring effective immune balance through the enhancement of Th1 capacity in the newborn is critical for protecting childhood health (Holt *et al.*, 2005; Yun and Lee, 2005). Prenatal maturation and functional skewing of the fetal immune system followed by the rapid reversal of the imbalance at birth have features that are not effectively modeled using adult exposure-assessment (Dietert and Piepenbrink, 2006b), and DIT is best viewed as a continuum of alterations. Suppression of the developing immune system, manifested as increased susceptibility to infections and cancer, is not the only concern, and immunotoxic changes that increase the risk for allergic or autoimmune responses in later life should also be considered (Edwards and Cooper, 2006; Selgrade *et al.*, 2006; Yeatts *et al.*, 2006). Adding to the complexity is the demonstration that some DIT seem capable of inducing targeted immune suppression while at the same time elevating the risk of allergy and/or autoimmunity (Haggqvist *et al.*, 2005). Because either significant immune suppression or disrupted immune regulation is a concern and needs to be detected, the most effective methodology for assessing DIT must also be capable of assessing significant changes in immune balance.

In spite of the increased interest in assessing the potential for developmental immunotoxicity, it must be emphasized that neither validated nor widely accepted methods currently exist for evaluating the effects of a chemical on the developing immune system. Several workshops have summarized consensus thinking concerning developmental immunotoxicity evaluation (Dietert *et al.*,

2000; Holsapple, 2002b; Holsapple *et al.*, 2005; Ladics *et al.*, 2005; Luster *et al.*, 2003; van Loveren and Piersma, 2004) and a number of reviews have been written (Burns-Naas *et al.*, 2008; Dietert and Burns-Naas, 2008; Dietert and Holsapple, 2007; Dietert and Piepenbrink, 2006b; Holsapple *et al.*, 2003, 2004, 2007; Luebke *et al.*, 2006a; Weinstock *et al.*, 2010; Winans *et al.*, 2011). Additionally, other reviews have dealt with issues concerning immunotoxicity evaluation across various life stages (Germolec *et al.*, 2004; Holsapple *et al.*, 2005; Ladics *et al.*, 2005; Ravel and Descotes, 2005). In light of the fact that neither validated nor established protocols presently exist to comprehensively assess whether a xenobiotic is a developmental immunotoxicant, below is a brief discussion of critical issues requiring consideration in establishing a testing framework.

In constructing a DIT testing framework, one of the first points to consider is the selection of an animal model. Consistently, the rat has been identified as the preferred species for evaluations of DIT, largely due to the fact that the rat has been utilized extensively in guideline developmental and reproductive toxicology testing. The anatomical and functional differences in the immune systems of the mouse, rat, dog, primate and human, and their use as models for DIT testing have been reviewed (Holsapple *et al.*, 2003). The review concluded that the developing immune systems of mice and humans have been best characterized to date. In addition, the review also concluded that immune ontogeny in the mouse and rat is likely similar. Another important consideration when selecting a species is that the development of the immune system in the rodent is delayed relative to the human, and how this differential maturation will impact data extrapolation for predicting human risk. For example, some developmental landmarks observed in utero in humans occur after parturition in the rat.

A second consideration when constructing a framework for assessing DIT concerns gender-specific effects. Results from perinatal exposure to xenobiotics suggest that significant sex-based differences in immunotoxic sensitivity are common and are at least as prevalent, if not more frequent, compared with the incidence observed following adult exposure-assessment (Dietert and Piepenbrink, 2006b; Luebke *et al.*, 2006a). As such, for the evaluation of DIT, testing of both sexes may be critical.

A third major consideration in a DIT testing framework is consideration of exposure. There is general agreement that the best exposure protocol is one where exposure occurs across all nonadult developmental windows followed either by immediate assessment or assessment after a few weeks (Holsapple *et al.*, 2005; Ladics *et al.*, 2005; Luster *et al.*, 2003). Exposure to pregnant dams has been a hallmark feature of most DIT protocols, and the maternal influences on exposure to the fetus/newborn pups would be dependent on transfer of the xenobiotic either across the placenta or via lactation. The gestational (eg, transplacental) and lactational periods in the rat would result in exposure from conception to early postweaning in the pup, approximately three weeks of age. Direct exposure of pups via the diet would generally commence at about three weeks after birth. An unresolved issue is whether direct exposure of the pups, which is generally accepted as a routine procedure at around postnatal Day seven, should occur during the lactational period as well (Ladics *et al.*, 2005); however, any decisions concerning this issue will require consideration of how humans would be exposed and the specific properties of the chemical being studied. For example, if exposure is only oral and there is no reason to believe that the lactational transfer differs significantly for a class of compounds between rats and humans, then direct dosing of pups could be initiated postweaning. In addition, information on pharmacokinetic and dosimetry could be useful in determining whether any

direct dosing of pups during lactation is necessary. However, it is important to emphasize that this type of information is not routinely available for most xenobiotics.

A fourth consideration in creating a DIT testing framework concerns which specific endpoints to measure. As discussed above, immune organs, such as the thymus, spleen, and/or bone marrow, are not typically assessed in routine developmental and reproductive toxicology studies, and it has been the consensus of a number of workshops that histopathological evaluation of these immune organs could be easily integrated into these existing protocols (Holsapple *et al.*, 2005; Luster *et al.*, 2003). However, presently, there is uncertainty whether routine histopathology is sufficiently sensitive to detect all potential immunotoxic effects, especially when the unique characteristics of the developing immune system, as discussed above, are considered. Indeed, there are examples where morphometric histopathological findings do not predict functional impairments due to toxicity produced on the developing immune system (Hussain *et al.*, 2005). Ultimately, while the use of specific, rather than general, histopathology has been recommended, it has been also suggested that functional tests be employed in the assessment of DIT. Unfortunately, few, if any, functional assays have been validated for detection of DIT, even for routine assays like the T-cell-dependent antibody response, which has largely been confined to adult exposure protocols. Results published on several chemicals and drugs in recent years suggest that functional tests are a front-line priority for perinatal immunotoxicity detection and that a combination of at least two functional tests, such as a multiisotype T-cell-dependent antibody response, and a CMI response assay, such as the DTH assay and/or CTL or NK cytotoxicity assays, should be paired with histopathological analysis and phenotypic analysis of lymphocyte subsets using flow cytometry (Dietert and Piepenbrink, 2006b).

One final point regarding the evaluation of developmental immunotoxicity needs to be considered. As developmental immunotoxicity protocols are inserted into existing toxicology testing regimes, such as developmental and reproductive toxicology protocols, it is likely to be necessary to incorporate immunization protocols. This approach has raised concerns among those evaluating other physiological systems (eg, reproductive and neurological) in terms of potential immunization-induced changes. However, investigations addressing this potential by determining the impact of the incorporation of immunotoxicological functional assays on standard toxicological studies in rats have been largely negative. Ladics and colleagues (1995) showed that immunization did not significantly alter the weights or morphology of routine protocol tissues with the exception of the spleen (ie, which manifested the anticipated increases in the numbers and size of germinal centers). In a subsequent study by this same group, immunization did not alter any hematological or clinical chemistry parameters, or lymphocyte subset numbers (ie, measured on peripheral blood with a flow cytometer), and did not mask the anticipated hepatotoxic effects of subchronic exposure to carbon tetrachloride (Ladics *et al.*, 1998). An additional component of this discussion is the reality that the species being modeled, the human, has immunizations as a routine lifelong component of preventative medicine. As such, to avoid all immunizations in animal evaluation protocols does not closely simulate the childhood experience. Additionally, until the immune system is asked to respond specifically to a foreign antigen, the capacity to detect immunotoxicity may be severely limited. Therefore, immunization and a range of functional T-cell-dependent immune response evaluations seem necessary as components of an effective DIT assessment.

Assessment of Hypersensitivity Responses As noted above, a primary role of the immune system is the discrimination of self versus nonself, and immunotoxicology can be thought of as a continuum with immunotoxic effects occurring in either direction (Fig. 12-1). The adverse consequences of exaggerated immune function would reflect an inability to recognize self, and are generally depicted as hypersensitivity and autoimmunity.

Drugs and chemicals that are capable of eliciting an immune response are generally low molecular weight substances possessing some inherent reactivity. There is a genetic susceptibility to hypersensitivity responses in that not all individuals react to the same drugs and chemicals. For the most part, the xenobiotic cannot be considered an antigen, simply because by itself it is not capable of stimulating an immune response. Instead, the xenobiotic often forms a hapten, which triggers the immune response in some tissue in the host. This property is called the sensitizing potential of the hapten and is associated with its inherent reactivity. Hapten-specific immune responses are therefore triggered only in the presence of the hapten-carrier complex and can be mediated either by humoral immunity or CMI. The damage associated with any type of hypersensitivity response can be directed against the tissue that is bound by the hapten. One of the most important and challenging problems in the field of immunotoxicology is determining the potential for chemicals to induce immune modulation and, in the current context, to demonstrate the sensitizing potential of xenobiotics. Thus, it becomes essential to have validated predictive animal models, and to understand the underlying mechanisms of action. The following is a discussion of the currently used methods of predicting the most frequently occurring hypersensitivity reactions to chemicals, Types I and IV, which are most often manifested as respiratory hypersensitivity and contact sensitization, respectively.

Assessment of Respiratory Hypersensitivity in Experimental Animals Methods for assessing the potential to induce respiratory hypersensitivity have been reviewed (Holsapple *et al.*, 2006). The objectives of this review were to describe the appropriate methods for identifying and characterizing respiratory hazards and risks and to identify the key data gaps and related research needs. The review addressed these objectives from the perspectives of proteins, chemicals, and drugs; and emphasized the important roles played by IgE and Th2 cell-mediated responses, while recognizing that damage to the respiratory tract can be triggered either by nonspecific irritation or by other specific (ie, non-IgE/Th2) immune-mediated mechanisms.

The state-of-the-science of animal models for respiratory hypersensitivity was also reviewed (Pauluhn, 2005). Current assays utilize two phases: induction/sensitization and challenge/elicitation. The induction phase usually includes multiple exposures to the test compound (sensitization) via the respiratory tract (ie, intranasal or intratracheal instillations, or by inhalation) or by dermal contact. There are advantages and disadvantages to each. Inhalation more closely represents environmental exposure by allowing for chemical contact with the upper as well as the lower respiratory tract. However, the equipment required is expensive and difficult to maintain. Exposure via the intranasal route is easily accomplished and allows for distribution of antigen to the upper and lower respiratory tract; however, studies have shown that a large proportion of the material can be recovered from the stomach (Robinson *et al.*, 1996). In contrast, intratracheal instillation results in exposure to the lower respiratory tract only. The observation that a predominant respiratory sensitizer would still trigger an IgE response when applied topically has suggested an important interplay between Type I hypersensitivity reactions, manifested primarily as respiratory sensitization, and

Type IV hypersensitivity reactions, manifested primarily as contact sensitization. The basis for this observation can be accounted for by a cytokine network model, which involves important cross talk between humoral immunity and CMI. Basically, a chemical with the capability of being a respiratory sensitizer will trigger an IgE response regardless of its route of exposure because it “selects” or supports the development of a Th2-dependent response, with the associated cytokine profile: IL-4, IL-5, IL-10, and IL-13. In contrast, a chemical which lacks the capability of being a respiratory sensitizer, but which can still trigger contact dermatitis, will select or support a Th1-dependent response, with the associated cytokine profile including IL-2 and IFN- γ .

The challenge (elicitation) phase involves exposure to the chemical (hapten), the homologous protein conjugate of the hapten, or the antigen. Endpoints to characterize a positive response range from the induction of Igs (ie, total IgE for chemicals or specific IgE for protein antigens), cytokines, or lymphokines in serum, to pathophysiological responses, including the influx of inflammatory cells and the onset of bronchoconstriction along with the associated changes in respiratory functional parameters. The latter may be accomplished by visual inspection of the animals' respiratory pattern or more quantitatively by plethysmography. With plethysmography, changes in the respiratory rate, tidal volume, and plethysmographic pressure can be measured. However, plethysmography in guinea pigs, rats, and mice can be technically challenging and labor intensive. In addition, there is some controversy over the interpretation of measurements made from whole body plethysmography, and whether these measurements truly reflect changes in airway mechanics (Lundblad *et al.*, 2002; Mitzner and Tankersley, 2003).

None of the currently applied animal models duplicates all features of human asthma, and most of the current animal models were developed for studying specific hypersensitivity responses to high molecular weight protein allergens (Pauluhn, 2005). Fewer animal models have been developed for use in the area of chemically induced respiratory allergy, which was one of the key data gaps identified in the review by Holsapple *et al.* (2006). One of the limitations associated with low molecular weight models is that often these compounds must conjugate with body proteins to become antigenic (ie, form hapten-carrier complexes). Often, a challenge with the conjugated chemical is necessary to induce a pulmonary response. Adding this variable can make the analysis of test results more difficult. False-negative results may occur due to variability in test article conjugation; and chemical conjugates are also necessary to measure specific immunological responses.

The majority of the current animal models are based on antibody-mediated events occurring as a reflection of the induction phase (Pauluhn, 2005). In certain cases, immunological sensitization may be confirmed by the detection of antigen-specific antibody; however, subsequent challenge does not produce clinical signs of respiratory distress. It is also possible to detect pulmonary sensitization in animal models where there is no detectable antigen-specific antibody production. In these cases, CMI or other mechanisms may be involved, or there may be difficulty in antibody detection.

Guinea pig models have been most frequently used for detection of pulmonary reactions to chemicals, because this species is known to respond vigorously to appropriate stimuli by developing an asthmatic-like bronchial spasm. In the guinea pig, as in the human, the lung is the major shock organ for anaphylactic response. Like humans, the guinea pig also demonstrates immediate- and late-onset allergic reactions as well as bronchial hyperreactivity and eosinophil influx and inflammation. The major difference in the mechanism of pulmonary responses between humans and guinea

pigs is that the antibody involved in Type I reactions in humans is IgE and in guinea pigs is predominantly IgG₁. The key features of this animal model involve protocols using single or repeated inhalation or cutaneous (ie, primarily topical or intradermal) exposures followed by a rest period until Day 21 (Pauluhn, 2005). After the rest period, an inhalation challenge with the hapten or antigen is performed thereby focusing on a measurement of the elicitation phase of the response (Karol *et al.*, 1994). Respiratory patterns are often measured in whole-body plethysmographs, as discussed above. A common pathological accompaniment of increased airway hyperactivity is prolonged eosinophil-rich inflammatory leukocyte infiltration into the lungs of guinea pigs after inhalation challenge of the protein or hapten-conjugate. One of the disadvantages of using guinea pigs is the lack of reagents needed to identify cell types and mediators involved in respiratory allergy, which has hampered mechanistic studies.

Murine models, in which reagent availability is not an issue, have become more frequently utilized in the evaluation of respiratory hypersensitivity, and two approaches have been described. The first approach capitalizes on the fact that, like humans, IgE is the major anaphylactogenic antibody in mice, and focuses on the induction of total serum IgE (Dearman *et al.*, 1998). The second approach capitalizes on the aforementioned cytokine network and has been referred to as cytokine profiling (Dearman *et al.*, 2002, 2003; Plitnick *et al.*, 2002, 2003). Both approaches have relied on dermal application of potential allergens/sensitizers, and on the theoretical foundation that chemical allergens induce divergent immune responses characteristic of the selective activation of discrete T-cell subpopulations (Pauluhn, 2005). Contact allergens, such as 2,4-dinitrochlorobenzene, are considered not to cause sensitization of the respiratory tract, and trigger an immune response in mice that is consistent with the preferential activation of Th1 cells (ie, little to no increase in total serum IgE and the production of IL-2 and IFN- γ in the draining lymph nodes). In contrast, topical sensitization to chemical respiratory allergens, such as TMA, triggers an immune response in mice that is consistent with the preferential activation of Th2 cells (ie, a moderate to marked increase in total serum IgE and the production of IL-4, IL-5, IL-10, and IL-13 in the draining lymph nodes). It is important to emphasize that while both the mouse total serum IgE test and cytokine profiling hold much promise, neither approach can be considered validated at this time.

Assessment of IgE-Mediated Hypersensitivity Responses in Humans Described below are methods of human Type I hypersensitivity testing. These test results, in conjunction with a relevant history and physical exam, can be diagnostic of IgE-mediated pulmonary disease. Two skin tests are available for immediate hypersensitivity testing. In both, the measured endpoint is a wheal and flare reaction (ie, the result of edema and erythema subsequent to the release of preformed inflammatory mediators). The prick-puncture test introduces very small amounts of antigen under the skin and, owing to the reduced chance of systemic reaction, is recommended as a screening test. For test compounds not eliciting a reaction, the intradermal test using dilute concentrations of antigen may be used, but there is a higher risk of systemic reactions. The reader is referred to an additional text for a more detailed description of testing methods (Demoly *et al.*, 1998).

In vitro serological tests, ELISAs, and radioallergosorbent tests may also be used to detect the presence of antigen-specific antibody in the patient's serum. These tests do not pose a risk of adverse reactions and may be used in situations where standardized reagents for skin testing are not available. Serological testing is often used in population-based epidemiological studies. Additionally, bronchial

provocation tests may be performed by having the patient inhale an antigen into the bronchial tree and evaluating his or her pulmonary response. In some cases, this may be the only way to demonstrate that a test article is capable of producing an asthmatic response. Care must be taken in these test situations in that it is possible to produce severe asthmatic reactions or anaphylaxis in sensitized individuals.

Assessment of Contact Hypersensitivity in Experimental Animals Classically, the potential for a chemical to produce contact hypersensitivity has been assessed by the use of guinea pig models. These tests vary in their method of application of the test article, in the dosing schedule, and in the utilization of adjuvants. For a description of methods employed in representative tests, refer to the study of Klecak (1987). The two most commonly utilized guinea pig models, the Buehler test (Buehler, 1965) and the guinea pig maximization test (Magnusson and Kligman, 1969), are described briefly below.

In the Buehler test, the test article is applied to the shaven flank and covered with an occlusive bandage for six hours. This procedure is repeated on Days 7 and 14. On Day 28, a challenge dose of the test article is applied to a shaven area on the opposite flank and covered with an occlusive dressing for 24 hours. At 24 and 48 hours after the patch is removed, test animals are compared with vehicle-treated controls for signs of edema and erythema. The guinea pig maximization test differs in that the test article is administered by intradermal injection, an adjuvant is employed, and irritating concentrations are used. Animals are given pairs of intradermal injections at a shaven area on the shoulders. One pair of injections contains adjuvant alone, one pair contains test article alone, and one pair contains the test article mixed with adjuvant. Seven days following injection, after the area is reshaven, the test article is applied topically and an occluded patch is applied for 48 hours. In cases where the test article at the given concentration is nonirritating, the area is pretreated with 10% sodium lauryl sulfate 24 hours before the patch is applied to produce a mild inflammatory response. Two weeks following topical application, the animals are challenged on the shaven flank with a nonirritating concentration of the test article, which remains under an occluded patch for 24 hours. Then, after 24 and 48 hours, the test site is examined for signs of erythema and edema, two well-recognized indicators of cutaneous inflammation and contact dermatitis. However, the endpoints for evaluation in the guinea pig assays are visual and subjective, and it is difficult to assess irritating or colored compounds using these models.

Over the past 20 years, efforts have been made to develop and establish more quantitative and immunologically based assay methods in other species, focusing mainly on the mouse, again primarily because of the availability of reagents and techniques to conduct mechanistic studies. Gad and coworkers (1986) developed the mouse ear swelling test, which uses a quantitative measurement of ear thickness as an endpoint. Animals are sensitized by topical application of the test article for four consecutive days to abdominal skin that has been prepared by intradermal injection of adjuvant and tape stripping. On Day 10, the animals are challenged by topical application of the test article to one ear and vehicle to the contralateral ear. Measurements are made of ear thickness 24 and 48 hours later. A positive response is considered anything above a 20% increase in thickness of the treated ear over the control ear. Thorne and colleagues (1991) showed that dietary supplementation with vitamin A enhanced the mouse ear swelling assay in the absence of adjuvants, injections, or occlusive patches.

The assays described above evaluate the elicitation phase of the response in previously sensitized animals. In contrast, the

mouse local lymph node assay (LLNA) identifies contact allergens as a function of the events occurring during the induction (sensitization) phase of a hypersensitivity response. The origins, development, evaluation, and eventual validation of the LLNA have been described in a comprehensive review (Kimber *et al.*, 2002). In this assay, the induction phase of contact sensitization is measured by the incorporation of ^3H -thymidine into proliferating lymphocytes in lymph nodes draining the site where the test article has been applied. Animals are dosed by topical application of the test article to the ears for three consecutive days. The animals are rested for two days and then injected intravenously with 20 μCi of ^3H -thymidine. Five hours later, animals are sacrificed, the draining lymph nodes are dissected out, and single-cell suspensions are prepared and radioassayed. With consideration of dose–response and statistical significance, a threefold increase in ^3H -thymidine cpm in chemically exposed animals over vehicle control animals (ie, the stimulation index) is considered to be a positive response.

The LLNA offers several advantages over the guinea pig assays in that (1) it has the potential to reduce the number of animals required and reduces animal distress; (2) it provides quantitative data that allow for statistical analysis; and (3) it provides dose–response data. The latter qualities of the LLNA have facilitated its integration into comparisons of potency across individual chemicals and/or within a chemical class. These additional advantages of the LLNA have facilitated its integration into risk assessments for contact dermatitis (Felter *et al.*, 2003). Additionally, because the LLNA evaluates the induction phase of the immune response, it is more applicable to mechanistic studies. As an example, some compounds capable of producing contact sensitization also induce IgE production and subsequent respiratory hypersensitivity. Using three known allergenic diisocyanates—diphenylmethane-4,4'-diisocyanate, dicyclohexylmethane-4,4'-diisocyanate, and isophorone diisocyanate—Dearman and coworkers (1992) showed that all three known contact sensitizers induced lymphocyte proliferation in the draining lymph node but that only diphenylmethane-4,4'-diisocyanate, a known respiratory sensitizer, induced elevated levels of serum IgE and IgG2b. These types of results have prompted a number of investigators to propose that the LLNA could be considered as the first step in a safety evaluation process for allergenic potential (ie, as a method to identify sensitization potential of a chemical) with other methods being deployed to distinguish between skin and respiratory sensitizing activity (Holsapple *et al.*, 2006).

Assessment of Contact Hypersensitivity in Humans Human testing for contact hypersensitivity reactions is by skin patch testing. Patch testing allows for the diagnostic production of acute lesions of contact hypersensitivity by the application of a suspected allergen to the skin. Patches containing specified concentrations of the allergen in the appropriate vehicle are applied under an occlusive patch for 48 hours in most test protocols. Once the patch is removed and enough time elapses for the signs of mechanical irritation to resolve (approximately 30 minutes), the area is read for signs of erythema, papules, vesicles, and edema. Generally, the test is read again at 72 hours and, in some cases, signs may not appear for up to one week or more. Detailed information on patch testing has been reviewed (Mydlarski *et al.*, 1998).

Human repeat insult patch tests are available as predictive tests in humans. Like predictive testing in animal models, there are many variations in attempts to increase the sensitivity of these procedures. These include preparation of the induction site by either tape-stripping, the application of an irritating concentration of sodium lauryl sulfate, or use of high concentrations of the test article for induction of sensitization. In general, the application of multiple occlusive

patches, up to ten for 48 hours each at the same site, is followed by a rest period and then a challenge takes place under an occlusive patch at a different site. Positive reactions are scored in the same manner as for diagnostic patch tests.

Assessment of Autoimmune Responses As described in the preceding section, exaggerated immune responses can be mediated by two entirely different types of interactions between the immune system and xenobiotics. One type of interaction was described in the preceding section in which the xenobiotic is a hapten, and the immune system plays an active role in eliciting a hypersensitivity response. The immune system can also be a passive target for the enhancing effects of drugs and chemicals, such as occurs when a xenobiotic mimics or causes the aberrant production of immunomodulatory cytokines, or when a xenobiotic disrupts the regulatory mechanisms which serve to protect self (ie, disrupt a suppressor mechanism). Additional mechanisms were presented above in the subsection "Autoimmunity" under "Immune-Mediated Disease."

Another way that xenobiotics can enhance immune function is by acting as an adjuvant, which is defined as any substance that nonspecifically enhances the immune response to an antigen. The classic adjuvant is complete Freund's adjuvant, which is a water-in-oil emulsion containing killed mycobacteria. The effectiveness of adjuvants in enhancing immune responses can be demonstrated by the fact that animals are often injected with complete Freund's adjuvant to increase the production of antigen-specific antibodies, and by the desire to develop an adjuvant that is safe in humans (ie, complete Freund's adjuvant produces severe side effects) that could be used in conjunction with vaccines or immunotherapy. The specific mechanisms for the actions of adjuvants, including complete Freund's adjuvant, are not known. Moreover, the existence of environmental adjuvants is controversial and/or poorly studied.

In the context of testing strategies, the situation with autoimmunity is much more complex than with hypersensitivity responses. Animal models exist for a number of autoimmune diseases, and autoimmunity has been clearly demonstrated in humans. Therefore, the existence of autoimmune disease and the expected consequences cannot be denied. However, the ability of drugs and chemicals to exacerbate or trigger autoimmune disease in either animal models or humans is poorly understood. In fact, of all the possible consequences of immunotoxicity, autoimmunity is unquestionably the least understood. Primarily because of the strong genetic component in the susceptibility to autoimmunity, deciphering the exact role of xenobiotics in the induction of these conditions has proven to be very difficult. The following is a brief review of some of the currently used methods of predicting the potential of a xenobiotic to trigger or exacerbate autoimmunity leading to an inappropriate immune response to self-tissue antigens that can be associated with the generation of autoantibodies and/or autoreactive T cells.

As emphasized throughout this chapter, immunotoxicology has evolved to the point where an ever-increasing number of studies are being conducted to characterize the immunotoxicity of a variety of xenobiotics using standard immunotoxicological parameters. Depending on the specific drug/chemical, the exposure conditions, the species being tested and the immune parameter being measured, the outcomes can be manifested as decreases, increases, or no effect. While there is no question that the most frequent observation has been immune suppression, there is also no doubt that some examples of immune stimulation have been reported, a profile consistent with the concept of immunotoxicology existing as a continuum (Fig. 12-1). However, this observation can trigger some important questions. Should a treatment-related increase in an immune parameter such as the T-cell-dependent antibody response be considered

an adverse response? Should an increase in the antibody response to a neoantigen be considered a harbinger of autoimmune potential? There simply is no consensus regarding the correct way to interpret an increase in immune parameters such as the T-cell-dependent antibody response, which were primarily developed to characterize the immunosuppressive potential of xenobiotics.

An assay that was specifically developed to characterize the immunostimulatory capacity of low molecular weight compounds (ie, pharmaceuticals in particular) is the popliteal lymph node assay (PLNA) (Kammuller *et al.*, 1989). The concept for this assay was originally proposed by Gleichmann and coworkers (1984), who speculated that graft-versus-host reactions might be the basis for the pathogenetic mechanisms behind the development of drug-induced allergy and autoimmunity. The primary approach to the PLNA is to inject compounds subcutaneously into the hind footpad of either mice or rats. After six to eight days, the draining popliteal lymph nodes (PLNs) are excised and compared with PLNs from vehicle-treated animals. Differences (eg, increase) in the weight or cellularity of the treated nodes are an indication of the immunostimulatory potential of the test compound. Over the past 20 to 25 years, more than 130 chemicals have been tested in the PLNA (Pieters and Albers, 1999), yet the assay can still not be considered to be validated. Intralaboratory studies with the PLNA concluded that this method might be able to detect drugs capable of causing human drug hypersensitivity with high prevalence; but that additional development is needed to increase the reproducibility of the PLNA and to increase detection of drugs that require metabolic activation to become allergenic, or drugs for which there is dose-limiting toxicity (Weaver *et al.*, 2005). The interpretability of the PLNA was increased by the integration of reporter antigens, trinitrophenyl-ficoll and trinitrophenyl-ovalbumin (Albers *et al.*, 1997; Gutting *et al.*, 1999). The reporter antigen PLNA differs from the standard PLNA in two ways. First, the reporter antigens are injected with the test substance under investigation. Second, anti-trinitrophenyl-specific antibodies are measured via ELISPOT, in addition to the comparisons of the PLNs. The profile of antibody production against the T-cell-independent antigen, trinitrophenyl-ficoll, and against trinitrophenyl-ovalbumin, an antigen recognized by T cells and B cells, enables the discrimination between immunosensitizing, and mere adjuvant or irritant potential of compounds.

The state-of-the-science of animal models of autoimmune disease has been summarized (Germolec, 2005). This review emphasized that while a wide variety of animal species have been studied, rodents have been most common, and concluded that rodent models fall into three categories: genetically predisposed animal models; animal models in which the autoimmune disease is produced by immunization with specific antigens; and animal models in which the disease is chemically induced.

Examples of genetically predisposed animal models include the nonobese diabetic (NOD) mouse, the F1 cross between the New Zealand black (NZB) and New Zealand white (NZW) mouse, and the MRL/lpr mouse. The NOD model has been used to study type 1 diabetes, specifically the T-cell autoimmune response, the role of B-cell antigen presentation, and the role of cytokines in the disease progression. The NZB × NZW F1 and the MRL/lpr mouse models have been used to study human SLE. The NZB × NZW F1 model has been used to map the specific susceptibility loci and to assess the importance of B-cell hyperactivity and T-cell involvement in autoantibody production in the development of SLE (reviewed by Germolec, 2005), while the important role of apoptosis in negative selection has been studied in the MRL/lpr mouse model, in which a genetic defect results in a mutation in the *Fas* gene. While both models exhibit characteristics of human SLE including high levels

of serum immunoglobulins (ie, antinuclear and anti-DNA antibodies), as well as the immune-mediated nephritis, the MRL/lpr mouse model also exhibits rheumatoid factor autoantibodies and inflammatory joint disease characteristic of an arthritic response.

Arthritis can also be induced in susceptible rat strains by immunization with complete Freund's adjuvant containing killed *Mycobacterium tuberculosis* in oil. Immunization of susceptible mouse strains (ie, those containing H-2^a or H-2^b alleles of the MHC) with type II collagen or cartilage glycoproteins, in the presence of adjuvant, can induce pathology similar to human rheumatoid arthritis. In collagen-induced models of arthritis, the immune response is directed against specific connective tissue antigens, while the complete Freund's adjuvant-induced response is directed against a mycobacterium heat shock protein, with the observed pathology resulting from cross-reactive destruction of a proteoglycan found in joints (Germolec, 2005). Experimental autoimmune encephalomyelitis can be induced in a number of species by immunization with myelin basic protein and complete Freund's adjuvant. This model has been used in rodents to characterize the role of T helper cell-mediated autoimmune disease characterized by perivascular lymphocyte infiltration of the CNS and the destruction of the myelin nerve sheath resulting in paralysis, similar to human multiple sclerosis.

One of the most commonly used models of chemically induced autoimmunity is the Brown Norway rat model, where animals are injected with mercuric chloride. While the selection of doses is such that exposure produces no overt signs of toxicity, Brown Norway rats develop an immunologically-mediated disease characterized by T-cell-mediated polyclonal B-cell activation, autoantibodies to laminin, collagen IV, and other components of the glomerular basement membrane similar to human autoimmune glomerulonephritis. Numerous mouse strains have also been used to evaluate the development of autoantibodies following exposure to mercury, gold, and cadmium (Selgrade *et al.*, 1999). Other examples of xenobiotics that have been demonstrated to be associated with autoimmune disease will be provided below.

Molecular Biology Approaches to Immunotoxicology As in all of the biological sciences, the continuing evolution of molecular biology-based methods and technologies have vastly expanded the tools available to immunotoxicologists. In general, molecular biology approaches have been thus far employed primarily in the investigation and elucidation of mechanisms of immunotoxicity rather than for identifying immunotoxicants. As these approaches become more refined and sophisticated with time, their application will surely expand. Presently, the primary application of molecular biology in immunotoxicology has been to identify genes whose expression has been altered by a xenobiotic, often termed gene expression profiling, and/or to quantify the magnitude to which gene expression has been changed due to some treatment. As already discussed, methods for assessing changes in gene expression have been particularly useful for studies of the immune system due to the fact that many of the immunological mediators produced by leukocytes (eg, cytokines, chemokines, and immunoglobulins) are regulated transcriptionally (ie, synthesized and secreted on demand) rather than being maintained in cells as stored products. Toward this end, quantitative reverse transcriptase-polymerase chain reaction (RT-PCR) has been the principal method currently used to assess changes in mRNA levels for specific genes in tissues and cells. With the development of real time RT-PCR, accurate quantification of gene-specific mRNA levels is readily achieved through the analysis of PCR kinetics by detecting products as they accumulate in "real time" through the application of fluorogenic

probes or double-stranded DNA binding dyes. Significant advantages of RT-PCR over traditional methods for analysis of mRNA levels, principally Northern blotting, includes accuracy, sensitivity, markedly less RNA required to conduct the analysis, and less time required to complete the analysis. Recent advances in thermocycler technology and the availability of commercial reagents currently permit the quantification of up to 384 genes from one RNA sample by employing what are termed "low-density" arrays. The technology takes advantage of plates comprised of 384 wells that have been precoated with primers for up to 384 specific genes of interest.

Another approach for conducting gene expression profiling by assessing changes in mRNA levels for multiple genes simultaneously has been through the use of cDNA microarrays. The approach facilitates the analysis of hundreds to tens of thousands of genes from a single RNA sample. The principal advantage of microarrays is the ability to assay mRNA levels for a large number of genes simultaneously. The primary disadvantages are the cost associated with microarray analysis, the complexity associated with data analysis and bioinformatics, and the sensitivity of the methodology to assess moderate changes in mRNA levels. In spite of these challenges, the application of microarray analysis in immunotoxicology has been increasing (Luebke *et al.*, 2006b).

A routinely employed methodology for characterizing effects on gene transcription has been the use of reporter assays. Reporter assays are being widely used to discern whether xenobiotic-induced changes in mRNA levels for specific genes are due to alterations at the level of transcription versus mRNA stability. Likewise, reporters can be used to characterize the effects of xenobiotics on specific transcription factors acting through defined regulatory elements. The approach involves construction of a DNA plasmid possessing the 5' untranslated regulatory region of the gene of interest that has been ligated to the translated region of a reporter gene. Commonly used reporter genes are typically enzymes, since their expression can be easily assayed. Moreover, studies in mammalian systems commonly employ reporter genes of insect or bacterial origin, thus eliminating the need to differentiate between endogenous and ectopic expression. The most widely used reporter genes are firefly luciferase and bacterial β -galactosidase. Most often, reporter assays are performed by transient transfection into cell lines. This approach has been extensively used to study the effects of leukocyte activation stimuli and xenobiotics on the regulation of promoter and enhancer regions of cytokine and Ig genes. In spite of the important mechanistic information that can be gained from these types of studies, significant challenges often arise in utilizing reporter assays to study leukocytes. Transfection of primary leukocytes, especially lymphocytes, yielding both high transfection efficiency and good cell viability is extremely difficult. An additional complicating factor concerns the fact that lymphocytes can only be maintained viable in culture for short periods (approximately 24 hours) in the absence of activation, which limits the duration the cells can be given to recover after transfection. Likewise, it is not uncommon for T- and B-cell derived lines to be resistant to transfection in spite of the many commercial transfection reagents presently available and new refinements made to electroporation instruments. In most cases, transfection conditions must be optimized for transfection efficiency and cell viability for each cell line or preparation using a control plasmid (ie, a plasmid possessing strong constitutive expression).

RNA interference employing small interfering double-stranded RNAs (siRNA) to achieve posttranscriptional gene-specific silencing is widely applied to investigations aimed at elucidation of mechanism of immunotoxicity. RNA duplexes of 21 nucleotides possessing two nucleotide 3' overhanging ends once transfected into

the cell incorporate into a nuclease complex known as the RNA-induced silencing complex (RISC). Through an ATP-dependent mechanism, the duplexes are unwound and separated into their sense and antisense strands. RISC is directed by the unwound antisense siRNA strand homologous to the target mRNA, which then undergoes cleavage by an endonuclease termed “Slicer.” The ensuing destruction of the target gene mRNA results in the posttranslational silencing of gene expression. This approach provides a rapid mechanism by which the involvement of a specific gene product can be linked to biochemical and functional events induced by a xenobiotic in a given cell type, including leukocytes (Sandy *et al.*, 2005). Major challenges in the application of this methodology can exist. First, identification of an effective siRNA is critical, as not all sites of a given mRNA being targeted will result in gene silencing. Numerous strategies and criteria have been developed to assist in the rationale design of siRNA (Jia *et al.*, 2006; Khvorova *et al.*, 2003; Schwarz *et al.*, 2003). Second, as with the transient transfection of reporters discussed above, leukocytes, and especially lymphocytes, are often resistant to transfection resulting either in poor delivery of the siRNA into the desired cell preparation or low viability. Since siRNA are most often used in cell lines, the doubling rate of the cells can significantly affect the level of knockdown achieved based on the fact that each time a cell undergoes replication, the cellular siRNA is diluted by half. The half-life of the protein can also significantly impact on the level of knockdown achieved even if large amounts of siRNA are delivered into the cells. Also, genes that are highly expressed can be difficult to effectively knockdown due to the large amount of mRNA that must be destroyed. Likewise, genes with very low expression can be difficult to silence as the odds of the RISC complex finding rare mRNAs in the cell may be low. Lastly, antibodies must be available to the gene product being targeted for knockdown so that the magnitude of knockdown can be confirmed at the protein level. In spite of these many potential challenges, the ability to effectively achieve gene-specific silencing, in some cases of a magnitude greater than 90%, is a remarkably powerful tool when elucidating biological mechanisms for which knockout mice are not available.

A relatively new area of research that has not yet had broad application to the field of immunotoxicology is proteomics. Proteomics can be defined as research that aims to identify, quantify, and classify the function of proteins produced by given genomes. In addition to the systematic identification and characterization of proteins, a potentially important application of proteomics is in the characterization of protein–protein interactions, especially as they relate to the elucidation of signal transduction mechanisms. Strategies have been proposed for the functional analysis of signal transduction, termed phosphoproteomics (Morandell *et al.*, 2006). Unfortunately, a major drawback in the application of proteomics includes the lack of an experimental platform currently available to systematically measure the diverse properties of proteins in a high-throughput approach. Presently, most proteomic methods are based on mass spectrometry and require expensive instrumentation, information-technology infrastructure, and highly specialized personnel. In addition, the complexity of the proteome is enormous as illustrated by Aebersold when he compared the human genome, which is comprised of approximately 30,000 genes, to human serum, which alone has been estimated to contain approximately 500,000 different protein species (Aebersold, 2003). Nevertheless, the application of proteomics to study proteins is occurring routinely in cell-based systems.

As stated above, the use of molecular biology based methods in immunotoxicology to date has been primarily for understanding mechanisms of action of known immunotoxicants. Much research

is currently focused on quantifying changes in mRNA levels (eg, cytokines) and elucidating mechanisms responsible for those xenobiotic-induced changes. Similarly, changes in mRNA expression profiles may be useful as possible biomarkers of exposure. Proteomics and genomics, combined with bioinformatics, are making it possible to evaluate chemically induced alterations in entire pathways and signaling networks. The utility of molecular biology tools such as proteomics and genomics in elucidating mechanisms of action is obvious. More challenging will be the application of these tools for identifying new or suspected immunotoxicants (Luebke *et al.*, 2006b).

Mechanistic Approaches to Immunotoxicology Once an agent has been identified as being an immunotoxicant, it may be necessary to further characterize the mechanism by which it exerts its effects on the immune system. Toward this end, a unique aspect of the immune system that greatly facilitates investigations aimed at delineating the underlying mechanisms of action is the ability to study the immune system in the intact animal as well as remove immune cells from the intact animal and have them function *in vitro*. Using a combination of these two approaches, a general strategy has been successfully employed by a wide number of laboratories for characterizing mechanisms of immunotoxic action by xenobiotics and involves the following steps: (1) identifying the cell type(s) targeted by the agent; (2) determining whether the effects are mediated by the parent compound or by a metabolite of the parent; (3) determining whether the effects are mediated directly or indirectly by the xenobiotic; and (4) elucidating the molecular events responsible for altered leukocyte function. The significance of each and the experimental strategies typically employed are discussed below.

Identification of the Cell Type or Type(s) Targeted With few exceptions, the first objective toward elucidation of the mechanism(s) responsible for immunotoxicity is the identification of the cell type(s) affected by the xenobiotic. The rationale is that the immune system is comprised of a wide variety of cell types with broad, and often, overlapping effector functions. Therefore, identification of specific cell type(s) affected allows for the selection of appropriate approaches and techniques to employ to further elucidate the mechanism of action.

The approaches available for the identification of the cell types targeted by a specific agent are numerous but typically originate with the employment of one or more of the functional assays within the immunotoxicology tier testing battery (see the “The National Toxicology Program Tier Approach” section later in this chapter). Each of the functional assays in the immunotoxicology tier testing battery provides information on accessory and/or effector cell function. For example, the AFC response to the T-cell-dependent antigen, sRBC, requires macrophages and CD4⁺ T cells (Th cells) to function as accessory cells, and B cells to serve as the effector cells. Therefore, if any one of these three cell types is adversely affected by an immunotoxicant, changes in the magnitude of the AFC response would be observed as compared to control (ie, enhancement or suppression). Similarly, the CTL response requires APC and CD4⁺ T cells (Th cells) as the accessory cells and CD8⁺ T cells, which are the effector CTL. Functional assays can be further refined to provide additional information concerning the targeted cell types by employment of various defined antigens requiring different cellular cooperativity to elicit an effector response. The AFC response has been especially useful in this respect. In addition to using a T-cell-dependent sensitizing antigen such as sRBC, T-cell-independent antigens can be employed including dinitrophenyl-ficoll or trinitrophenyl-LPS, which require macrophages, but do

not require T cells, to elicit an antibody response. Likewise, B cells can be driven to differentiate into AFC in the absence of accessory cells using polyclonal B-cell activators such as LPS. By employing the three different types of antigens in order to characterize a xenobiotic, a profile of activity emerges that can distinguish between effects on the B cell, T cell, and APC.

As described in the examples above, when accessory cells are required in the elicitation of an immune response, it is often difficult to discern whether alteration of an immune response is due to the xenobiotic targeting the effector cell population or one or more of the accessory cell populations. Under such circumstances, another strategy utilized for identifying the cellular targets is a cell fractionation–reconstitution approach. Specifically, leukocytes can be isolated from treated and vehicle control animals, typically mice, and fractionated into their respective populations. The fractionated cell populations from vehicle and treated animals can then be reconstituted in various combinations to be used in functional assays to determine the population of cells that has been altered. A comprehensive discussion of the various methods that can be used to fractionate leukocyte populations and subpopulations is beyond the scope of this chapter; however, two of the most common approaches to fractionate leukocyte populations are briefly described here. The first is by cell sorting using flow cytometry. The primary advantage of this approach is that it yields an exceptionally high purity of cell populations and subpopulations. The primary disadvantages include: (1) access to a high-end flow cytometer; (2) cost of reagents and trained personnel capable of operating a flow cytometer; (3) practical limitations concerning the total number of cells that can be collected within a reasonable period of time due to the rate at which the instrument analyzes and collects the cells; and (4) positive selection (ie, the cells are bound by a cell-specific antibody) is used for identifying the desired cell population being collected. The second and more commonly used approach utilizes antibodies directed at surface antigens unique to specific leukocyte populations and subpopulations that have been covalently conjugated to magnetic beads. Using the conjugated magnetic beads and a magnet, large numbers of highly pure cell populations can be isolated rapidly, by positive or negative selection, without requirements for expensive instrumentation. As with the cell sorting approach, purified population of cells isolated from vehicle and treated animals can be isolated and reconstituted in various combinations for evaluation in functional assays.

Determination of Whether Immunotoxicity is Mediated by the Parent or by a Metabolite of the Parent Compound A critical aspect in the elucidation of the mechanism of toxicity for any compound, regardless of the target or tissue is whether the adverse effects are mediated by the parent form of the compound or its metabolite. An understanding of the role of metabolism is especially critical when studying immunotoxicants as it will dictate the experimental approaches that can be utilized. In general, leukocytes possess very modest levels of drug-metabolizing enzymes, especially those within the cytochrome P450 family. Therefore, those agents that are metabolically bioactivated to an immunosuppressive form will in most cases not exhibit their immunotoxic profile of activity when added directly to cultured leukocytes. In fact, an important indication that metabolic activation may be a requisite mechanistic event is the observation that an agent is immunotoxic following *in vivo* administration while exhibiting no immunotoxic activity when added directly to cultured leukocytes. An example of such an agent is the therapeutic agent, cyclophosphamide. When administered *in vivo*, cyclophosphamide is a potent immunosuppressant that preferentially suppresses humoral

immune responses while having no effect when directly added to cultured leukocytes.

In order to assess whether metabolic bioactivation is required for immunotoxicity, several different approaches can be employed. One approach is to determine whether pre- or co-treatment with either an inducer or an inhibitor of the enzymes known to be involved in the metabolism of the agent modify the immunotoxicity produced *in vivo*. Similarly, *in vitro* approaches have also been used to assess the role of metabolism for an immunotoxicant. Specifically, these approaches utilize various *in vitro* metabolic activation systems such as S9 liver homogenates or isolated liver microsomes, which can activate the xenobiotic when incorporated with leukocyte cultures. Alternatively, freshly isolated primary hepatocytes can be cocultured with leukocytes in the presence of the xenobiotic. Although primary hepatocytes most closely simulate the metabolic activity observed *in vivo*, this approach is also the most technically challenging since the approach is critically dependent on the isolation of viable and metabolically active hepatocytes. Cyclophosphamide is typically employed as a positive control in all three of the aforementioned *in vitro* activation systems to confirm metabolic activity. The metabolic activation systems discussed above can also be employed for conducting mechanistic studies *in vitro* that cannot be performed in the intact animal to further characterize immunotoxicants requiring metabolic bioactivation.

Determination of Whether the Effects are Mediated Directly or Indirectly by the Xenobiotic or a Metabolite of the Xenobiotic

In most instances, immunotoxicants mediate their effects by interacting directly with the immune system. These direct actions may include structural alterations in lymphoid organs or on the cellular composition of lymphoid organs, on the expression of regulatory molecules on the immune cell surface, and/or by altering intracellular biochemical or molecular events (Table 12-8). However, some xenobiotics mediate changes in immune competence through an indirect action on the immune system. Under these circumstances, changes in immune competence are mediated through the release of an immunomodulatory factor resulting from the actions of the immunotoxicant on cells or tissues other than the immune system. One tissue most often implicated in indirectly modulating the immune system is the liver, as it is the source of a broad and extremely diverse group of proteins, including acute-phase proteins. Acute-phase proteins are a family of serum proteins produced by the liver in response to inflammation or infection (see the “Inflammation” section). Acute-phase proteins are believed to have evolved as part of an immediate survival response to systemic infection. In general, acute-phase proteins are associated with downregulation of the immune system and are therefore believed to play a role in maintaining immune homeostasis. The acute-phase proteins most extensively characterized with respect to immunomodulating properties include α -fetoprotein, serum amyloid A, and C-reactive protein. Another important group of regulatory proteins involved in indirectly modulating the immune system are those that contribute to the repair and regeneration of the liver after acute injury; specifically, TGF- β 1 and hepatocyte growth factor. A second example of indirect actions on the immune system is stress as well as agents that alter the regulation of the hypothalamic–pituitary–adrenal axis, thus leading to changes in hormonal homeostasis. Deregulation of hormonal homeostasis, especially increased circulating levels of glucocorticoids, can markedly decrease immune competence.

The elucidation of indirect mechanisms of action by an immunotoxicant can be challenging by virtue that the effect is indirect

Table 12-8

Possible Mechanisms of Chemical-Induced Immune Modulation

TYPE OF EFFECT	MECHANISM	EXAMPLES
Direct	Functional changes	Altered antibody-mediated responses Altered cell-mediated responses Altered release of preformed mediators Altered host resistance Inability of one or more cell types to perform a required activity, for example: Production of antibody Release of cytokines Processing and presentation of antigen Proliferation and differentiation Receptor-mediated signal transduction
	Structural changes	Alterations in surface receptors or ligands Alteration in expression of receptors or ligands Histopathological changes in lymphoid organs
	Compositional Changes	Alterations in CD3 ⁺ , CD4 ⁺ , CD8 ⁺ , B220 ⁺ , and/or Ig ⁺ in spleen Alterations in CD4 ⁺ , CD8 ⁺ , CD4 ⁺ /CD8 ⁺ , and/or CD4 ⁻ /CD8 ⁻ in thymus Changes in hematological cellular parameters Alterations in circulating Ig Alterations in CFU profile in bone marrow
	Metabolic activation	Conversion to a toxic metabolite
Indirect	Effects secondary to other target organ toxicity	Induction of acute-phase proteins as a result of liver injury Increased corticosteroid release from the adrenal gland
	Hormonal changes	Alteration in neuroendocrine regulation Alteration in autonomic output from the CNS Altered release of steroids from sex organs

and mediated by one or more circulating immunomodulatory serum factors. The involvement of an immunomodulatory serum factor can be partially deduced by two distinguishing features. First, the profile of immunotoxicity observed after *in vivo* administration of the causative agent is different from that produced by its direct addition to leukocytes in culture. Second, the profile of immunotoxicity observed after *in vivo* administration of the agent can be mimicked by direct addition of serum from the treated animal to naive leukocytes in culture. Third, the involvement of a metabolite of the parent form of the chemical has been ruled out. Confirmation of the involvement of a specific serum factor is most often accomplished *in vitro* by abrogating the immunotoxic activity produced by serum from treated animals using neutralizing antibodies directed against the suspected serum factor.

Elucidation of the Molecular Mechanism Numerous methodologies are available to evaluate cellular and molecular mechanisms of action and those continue to increase with the availability of new “omics” technologies, new animal models including transgenic and knockouts, and an ever-expanding list of reagents and molecular probes. Due to the broad nature of this topic area, this section is devoted to a general discussion of considerations and strategies aimed at the elucidation of molecular mechanisms. The discussion will be directed at B cells and T cells for illustrative purposes, but is certainly applicable to other cell types comprising the immune system.

When considering the molecular mechanism by which a xenobiotic alters the function of a mature lymphocyte, a practical strategy is to first identify at which stage of leukocyte function the agent is acting, antigen recognition/signaling through the antigen receptor, activation, proliferation, or differentiation. As discussed in the earlier sections of this chapter, lymphocytes have evolved

a number of specialized mechanisms by which B and T cells recognize antigen. Common to both cell types is that immediately after recognition of an antigen, there are a number of biochemical events triggered, including changes in protein phosphorylation and activation of a variety of kinases, fluxes in ions, and changes in the level of cyclic nucleotides. Because lymphocytes undergo a rapid and robust rise in intracellular calcium almost immediately after antigen–receptor binding, changes in calcium flux prior to and immediately following stimulation by an antigen provide important insights into whether an agent alters the most proximal stage of leukocyte function. Similarly, changes in the phosphorylation status of the intracellular domain of membrane-associated proteins (CD3 complex, CD4 and CD8 on T cells, and CD79, CD45, and CD22 on B cells) and the kinases that mediate the phosphorylation (eg, *lyk* and *fyn*) can be investigated to study the most proximal events associated with triggering of antigen receptors. Polyclonal activators are often employed to simultaneously activate large numbers of lymphocytes facilitating the evaluation of changes in these early biochemical events. For B cells, antibodies directed against the BCR in combination with CD40L can be used. Conversely, for T cells, antibodies directed against the TCR/CD3 complex and the coreceptor CD28.

The stage termed lymphocyte activation is functionally defined and refers to that period that begins when the T cell has initiated a response to an activation stimulus and ends when there is robust transcription of the T-cell autocrine/paracrine growth factor, IL-2 and upregulation of proteins on the cell surface including CD40L, CD69, and CD25 (alpha chain of the IL-2 receptor). In B cells, it is the period that begins with the cell responding to an activation signal culminating in the upregulation of activation markers CD80 (B7.1), CD86 (B7.2), CD69, and increased MHCII. All of the aforementioned changes associated with B-cell

and T-cell activation, including IL-2 synthesis, can be readily monitored and quantified in individual cells by flow cytometry. Investigations directed at elucidating the molecular events deregulated by xenobiotics during lymphocyte activation represent one of the most intensively studied areas presently in immunotoxicology as many different immunotoxicants affect this stage of lymphocyte function.

Clonal expansion is a critical phase of the immune response as it insures that a sufficient number of antigen-specific B- and T-effector cells are generated to respond effectively to combat a pathogen. In light of the importance of clonal expansion in mounting an effective immune response, the effect xenobiotics exert on lymphocyte proliferation has been widely used to determine whether a xenobiotic has immunotoxic properties. As with measurements directed at other stages of the immune response, it is often convenient to employ polyclonal B- and T-cell activators for investigating effects on proliferative responses. Due to a significant increase in the understanding of the cell cycle, coupled with the availability of reagents for measuring specific proteins involved in the regulation of cell cycle, it is now possible to functionally characterize and dissect the mechanism and specific intracellular targets affected by xenobiotics that disrupt lymphocyte proliferation. Measurements of changes in cell-cycle-associated regulatory proteins are most commonly achieved by employing flow cytometric approaches.

The final stage of the immune response involves differentiation into a mature effector or memory cell. For B and T cells, terminal differentiation into effector cells can be best assessed by measurements of effector function in conjunction with the upregulation and downregulation of proteins on the cell surface. Antibody production and upregulation of CD138 (also known as syndecan-1) are most often used as indicators of B-cell differentiation into effector cells while either cytokine production (Th cells and CTL) or lysis of target cells expressing viral or tumor proteins (CTL) are used to indicate T-cell differentiation. A number of commonly used immune function methods for assessing B- and T-cell effector functions were described earlier in this section.

Once the specific stage of lymphocyte function being altered by a specific xenobiotic has been established, experiments can be designed to identify the specific intracellular proteins affected by the xenobiotic and the molecular mechanism by which it is modulated. Cell line models can be invaluable tools for studies involving cell signaling and gene regulation.

Cell Line Models in Immunotoxicology Cell line-based models are being widely used for identifying agents possessing the potential of producing immunotoxicity as well as for conducting in-depth investigations aimed at elucidating molecular mechanisms for immunotoxicity. Significant advantages and disadvantages exist when applying cell line-based models, some of which are unique to investigations of the immune system. A brief discussion of the strengths and limitations of cell line-based models in the context of studies of immunotoxicants is provided below.

Although there are many advantages to cell line-based models, the most important characteristic is that all of the cells are derived from the same clone thus providing a homogenous cellular preparation. The homogeneity of the model is especially useful for studies directed at characterizing signal transduction pathways as well as gene expression profiling due to the greater likelihood of obtaining reproducible results. There are a number of advantages of cell line-based models that are especially useful in immunotoxicology. Primary leukocytes whether isolated from blood or lymphoid organs are highly heterogeneous in their cellular

composition. Purification of these primary cell preparations into specific cell types is expensive, can be labor intensive and with most isolation methods typically yielding 50% to 75% efficiency (ie, 25%–50% of the desired cells are lost during the purification process). Purification efficiency can become a critical issue when utilizing small rodents such as mice where the number of animals per assay can be significantly increased due to the loss of cells being recovered in the cell isolation procedure. When employing cell line models, typically there is no limitation on the number of cells available for a given study. Another important consideration in the case of primary lymphocytes is that they are only viable in culture for relatively brief periods of time (approximately 24 hours) in the absence of an activation signal. Therefore, extended preincubation periods in culture with an immunotoxicant or other response modifiers that do not activate primary lymphocytes cannot be performed. Primary leukocytes, especially lymphocytes, are also difficult to transfect, often yielding poor transfection efficiency and/or viability. The combination of poor transfection efficiency and limited culture duration in the absence of activation make reporter assays, transient ectopic gene expression, and utilization of siRNA to silence gene expression challenging in primary lymphocytes. Conversely, cell line-based models, especially of the lymphoid lineage, in most cases can be readily transfected with suitable efficiency and viability to conduct reporter assays, ectopic gene expression, and gene silencing with siRNA. It is noteworthy that primary cells of the myeloid lineage are more suited for long-term culture- and transfection-based experimental approaches as they have less stringent requirements for activation to be maintained in culture for extended periods. In such instances, it may be more advantageous to employ primary cells. Lastly, cell line-based models are also now being widely adapted for high-throughput screening due to the reproducibility of results obtained with these models and the ease in which cell lines can be maintained and manipulated.

In spite of the advantages discussed above, there are numerous disadvantages and limitations inherent in utilizing cell line models for characterizing immunotoxicants. The most important consideration when utilizing cell line models is that by definition, a cell line is an abnormal population of cells that has undergone a change rendering it capable of dividing indefinitely in culture. Since cell lines are continuously dividing, in most cases they are not good models for studying immunotoxicants that act by altering cell proliferation and/or regulators of the cell cycle. The aberrant nature of cell lines may also extend to a loss of function through one or more of its cognate receptors. Lastly, it is critical that cell lines are carefully monitored and characterized for changes in function and morphology after repeated passage in culture. Additional important considerations when selecting a cell line for mechanistic studies are the capacity of the cell line to perform a given effector function and the stimuli to which the model will respond. Toward this end, a number of cell lines have been extensively characterized and widely utilized that are capable of induced effector functions including cytokine production, antibody secretion, and release of a wide variety of mediators. Table 12-9 provides examples of some commonly used cell lines in immunotoxicology. As discussed above, with some cell lines, induction of an effector function may only be achievable by using pharmacological activators (eg, phorbol ester plus calcium ionophore) that bypass extracellular receptors or by agents that are polyclonal activators (eg, LPS) that do not activate directly through antigen receptors. Again these are characteristics of the models that need to be considered in the context of how the models will be used and for what specific purpose. In most cases, the utilization of cell line-based models can be extremely useful but results should always

Table 12-9

Cellular Models for Immunotoxicology

CELL LINE	CELL TYPE	SPECIES	EFFECTOR RESPONSE	STIMULUS
EL4	T cell	Mouse	IL-2	Phorbol ester
Jurkat E6	T cell	Human	IL-2	Phorbol ester + Ca ionophore or anti-CD3 + anti-CD28
CHI2.LX	B cell	Mouse	IgM	LPS
BCL-1	B cell	Mouse	IgM	LPS
SKW	B cell	Human	IgM	LPS or α IgM + CD40L
Daudi	B cell	Human	None (signal transduction)	α IgM
RAW 264.7	Macrophage	Mouse	Nitric oxide, IL-1	LPS
J774.1	Macrophage	Mouse	Nitric oxide, IFN- γ	LPS
U937	Macrophage	Human	TNF- α , IL-1 α , IL-6, IL-8	LPS

be confirmed, when possible, in primary leukocytes since cell lines are aberrant models.

Animal Models: Transgenics, Knockouts, and Humanized/Severe Combined Immunodeficient The developments in molecular biology have not only permitted the evaluation of specific genes or arrays of genes but have also allowed for the manipulation of the embryonic genome, creating transgenic, and knockout mice (reviewed by IPCS, 1996). As a consequence of transgenic technology, complex immune responses can be dissected into their components. In this way, the mechanisms by which immunotoxicants act can be better understood. Mice engineered to express nonself genes (eg, human MHC I) or overexpress self genes (eg, constitutively active transcription factors) are termed “transgenic,” and can be used to address the role of a certain protein in immunotoxicology. On the other hand, mice lacking certain proteins (eg, receptors, transcription factors, or cytokines) are termed “knockouts,” and can be used for similar mechanistic studies. Numerous transgenic and knockout mice have been created and are available to investigators worldwide. Of particular interest and potential utility in the area of immunotoxicology is what has been termed “humanized” mice. Humanized mice refer to immune-deficient mice that have been reconstituted either with human HSC to support a fully human immune system, or with mature cells to evaluate immune regulation, hematopoiesis, hypersensitivity, and autoimmunity. Severe combined immunodeficient (SCID) mice, which are mouse T- and B-cell deficient due to a VDJ recombination defect, are a major strain into which human immune cells/system are established. In addition, SCID mice are backcrossed with other strains in order to eliminate various arms of the immune system (eg, β 2M^{null}/SCID eliminate MHC I interactions) prior to reconstitution with human cells (reviewed by Thomsen *et al.*, 2005). Although their use in mechanistic studies is obvious, SCID/hu mice have also been utilized for evaluation of efficacy of antiviral drugs for HIV/AIDS (reviewed by Taggart *et al.*, 2004). There are still considerations, however, for broader application of these humanized mouse models for immunotoxicological assessment of compounds. For instance, one must consider how these animals compare with standard animal models with respect to time course of action, dose response, pharmacokinetics, and other factors of chemical toxicity. With the hope that these humanized mouse models can be used to identify new or suspected immunotoxicants, and mechanisms of action, one must also consider whether they are as sensitive, predictive, and/or cost-effective as traditional animal models.

Approaches to the Assessment of Human Immunotoxicity

As emphasized throughout this chapter, animal models have been extensively utilized to characterize immunotoxicity, and it is widely recognized that chemicals that produce immunotoxicity in animals have the potential to produce immune effects in the human population. The increasing emphasis on human risk assessment requires that those potential health hazards be identified whenever possible. In spite of the significant homology of the rodent and human immune systems which has facilitated our ability to make decisions on the immunotoxic potential of test materials based on the results of these experimental models (House, 1997), there is also an increasing recognition of distinct, although often subtle, differences in the composition of the immune system between animal species. These differences have primarily come to light in studies of leukocyte subpopulations, the phenotypic markers they express, and by the regulatory factors they secrete. Whether these differences in immune system composition result in significant differences across species in sensitivity to immunotoxicants is unclear. It is important to emphasize that to date there are no known cases of significant human immunotoxicity that has resulted due to false-negative results from rodent-based immunotoxicity testing. In contrast, there is extremely limited human immunotoxicology data on test materials other than those directly intended for human immunotherapy.

One of the obvious and most important goals of an experimental immunotoxicity testing strategy is to enable the best extrapolations between the results generated in the animal models and the potential risk of immunotoxicity in humans. A parallelogram approach has been used to assess relationships between animal data and human data (Selgrade, 1999; van Loveren *et al.*, 1995) and an adaptation of which is presented in Fig. 12-21. The overall strategy is to utilize *in vivo* and *in vitro* data from animal studies and *in vitro* data using human leukocytes in order to predict the *in vivo* effects of an immunotoxicant in humans. This approach has been used to extrapolate animal to human data in an initial quantitative assessment of the risk for deleterious effects of UV radiation (van Loveren *et al.*, 1995) and of the immunotoxicity associated with exposure to bis(tri-*n*-butyltin)oxide (van Loveren *et al.*, 1998). A parallelogram approach has also been used to propose that data for ozone suggest that effects of *in vivo* human exposure to phosgene on alveolar macrophages phagocytosis may be predicted based on effects of *in vitro* exposure and *in vivo* animal data (reviewed by Selgrade *et al.*, 1995).

Figure 12-21. Parallelogram approach in immunotoxicology for relating animal and human data. Immune in vitro data are often available for animals and humans. However, much of human immunotoxicity risk must be estimated from human in vitro studies and animal in vivo studies.

In spite of these successful applications of the parallelogram approach, it is recognized that extrapolations of alterations in immune function observed in animals to human health is associated with various uncertainties (House, 1997). For example, experimental animals are often inbred, which certainly lessens interanimal variability thereby simplifying the statistical evaluation of observations. Additionally, laboratory studies in rodents are highly controlled for environment, diet, and health status. In contrast, humans are a highly outbred species with a high degree of interindividual variability in immune response, and any human study must take into account extreme variability in all of the controlled parameters. In fact, it has been estimated that the overall immunocompetence of the individual is affected by age, gender, genetic factors, use of certain medications, drug/alcohol use, smoking history, stress and nutritional status, and that these factors can account for variability of more than two standard deviations in the “normal” human population (Luebke *et al.*, 2004). Luster *et al.* (2007) have speculated that the major gap in clarifying the shape of the dose–response curve (ie, between immune response and disease) is a lack of large-scale epidemiological studies in populations with mild-to-moderate immunodeficiency that have been monitored for immune system parameters and clinical disease taking into account potential complications by nonimmune factors which can affect infectious disease incidences.

Nonetheless, there is a clear association between suppression of immune function and an increased incidence of infectious and neoplastic disease in humans (reviewed by Biagini, 1998). However as noted above, a major limitation of immunotoxicity risk assessment has been the lack of human data (Descotes, 2006). In the context of xenobiotics, the majority of such data comes from immunotherapeutic drugs, which were intentionally designed to influence the immune system. The aforementioned association has been established primarily with a standard battery of parameters used extensively in clinical immunology studies, including routine complete blood counts and differentials, phenotypic characterization of surface markers and more detailed analysis of cellular subsets using a flow cytometer, lymphoproliferative assays (ie, using a number of stimuli including mitogens such as Con A and PHA,

recall antigens such as tetanus toxoid, anti-CD3 monoclonal antibody, and allogeneic lymphocytes in an MLR), and DTH responses using a test panel of recall antigens. In contrast with the clear association demonstrated for drugs used to deliberately suppress immune function or treat cancer, the assessment of immunotoxicity in humans exposed to potentially immunotoxic chemicals is much more complicated than in experimental animals (reviewed by IPCS, 1996). One of the fallouts of this observation has been the recognition that the historic approaches that have been used in clinical immunology may not have much use in human immunotoxicology. While these endpoints are sufficient to detect immunodeficiencies associated with either congenital disorders or immunosuppressive drug therapy, they do not possess the necessary sensitivity to detect the more subtle consequences of xenobiotic-induced immunotoxicity. Interestingly, Luebke *et al.* (2004) noted that in contrast to individuals with severe forms of primary or secondary immunodeficiency in whom infections to opportunistic pathogens (ie, members of the herpes viruses family, certain protozoans, *Candida albicans*, a yeast, and *Pneumocystis carinii*, a fungus) are seen, humans with low to moderate suppression of immune function are more susceptible to infection with pathogens associated with infections common in the general population (ie, encapsulated bacteria like *Streptococcus*, and influenza viruses). As a result, several proposals have been put forth to reevaluate the way that we measure immune function in humans. Most of these testing strategies have incorporated plans to measure the primary response to a new antigen, and several of these testing strategies have recommended using newly developed vaccines as the new antigen (van Loveren *et al.*, 2001). Vaccine response rates have been successfully used to characterize the impact of chronic stress on human immunocompetence (Glaser *et al.*, 2000; Kiecolt-Glaser *et al.*, 1996). Importantly, in spite of the limitations in human data, there is no question that environmental chemicals are associated with immunotoxicity in humans (Selgrade, 2007; Veraldi *et al.*, 2006).

It is anticipated that the development, validation, and utilization of more predictive methods to assess immunotoxicology in humans will be increasingly important in the future. Notably, the application of the parallelogram approach—by definition—requires the ability to measure immunotoxic effects using in vitro approaches with human lymphocytes. As described in another section of this chapter, human lymphocytes have been previously applied to study the effects of dibenzo-*p*-dioxins (Lu *et al.*, 2011, 2010; Wood and Holsapple, 1993; Wood *et al.*, 1993). Partly because of the recognition that investigations conducted exclusively using in vitro and in vivo animals models may not always be predictive of toxicity in humans (Selgrade, 1999; Vos and van Loveren, 1998), and partly because of the tremendous increase in the development of new drugs that are known to, or suspected of targeting the human immune system as discussed elsewhere in this chapter, there has been increasing interest in establishing predictive in vitro methods using human lymphocytes. A polyclonal IgM AFC response model was developed using the combination of CD40 ligand (CD40L) plus recombinant cytokines because it effectively drives both primary human and mouse B cells in a physiologically relevant manner to mimic T-cell-dependent antibody responses in vivo (Lu *et al.*, 2009). A second assay, the human lymphocyte activation (HuLa) assay, was developed that measures an influenza antigen-specific response using frozen-stored human peripheral blood mononuclear cells (PBMC) (Collinge *et al.*, 2010). Although proliferation is the primary endpoint in the HuLa, flow cytometry approaches can be used to characterize the proliferating lymphocyte subsets (eg, CD4⁺ and CD8⁺ T lymphocytes and B lymphocytes), and ELISPOT can

be used to measure influenza-specific AFC. A third *in vitro* model, termed MIMIC (*Modular IMune In vitro Construct*), uses the circulating immune cells of individual donors to recapitulate each individual human immune response by maintaining the autonomy of the donor and represents a physiologically accurate model of the human immune system (Higbee *et al.*, 2009). Interestingly, a version of MIMIC was recently used to investigate the immunopotency of a number of TLR agonists on DC generation, maturation, and antigen-presenting capacity (Ma *et al.*, 2010). Importantly, all three of these models have been used to characterize the dose–response characteristics and potency of a number of immunosuppressive drugs and nondrug chemicals.

For illustrative purposes it is useful to briefly compare and contrast the *in vitro* T cell-dependent IgM AFC response, which uses mouse spleen cells and is often considered one of the “gold standard” assays for characterizing immunotoxicants, to the human CD40L-induced IgM AFC assay, which utilizes purified HPB B cells. Unlike the widely used T-cell-dependent IgM AFC response assay, which uses a heterogeneous leukocyte preparation from the mouse spleen and sRBC as the sensitizing antigen, the CD40L drives IgM production using purified HPB B cells or primary mouse B cells, thus allowing for direct comparisons of sensitivity of immunotoxicants between mouse and human B cells (Lu *et al.*, 2009). It is important to emphasize that there are a number of significant and fundamental differences between the sRBC IgM AFC response and the CD40L-induced IgM AFC response. The most significant is that the CD40L response has no accessory cell involvement (ie, T cells or APC) since CD40L stimulation is provided either through the direct addition of rCD40L or by coculturing B cells with a genetically engineered CD40L-expressing fibroblast cell line (CD40L-L cells) plus recombinant T-cell cytokines. Therefore, the CD40L assay only provides information on B-cell function. In contrast, the sRBC IgM AFC response assay, in addition to B cells, requires functional T cells and APC for IgM production. From the perspective of hazard identification, the sRBC assay has greater capacity to detect immunotoxicants since in addition to B cells, the interactions of two other cell types and their consequent accessory cell functions are required in comparison to the CD40L assay. However, mechanistically, modulation of the CD40L-induced IgM response provides definitive identification of B-cell immunotoxicants and is an assay system in which mechanisms of B-cell immunotoxicology can be investigated in the absence of potential confounders associated with the presence of other cell types. In fact, using CD40L plus cytokines, the effects of immunotoxicants on B cells can be studied temporally throughout the entire continuum from activation to differentiation using flow cytometry. Another significant difference between the sRBC and the CD40L-induced IgM response is that the former is an antigen-specific response and the latter is not. In fact, presently there is no established antibody assay that employs human primary leukocytes to drive a primary, antigen-specific, T-cell-dependent antibody response. One of the major challenges in establishing such an assay is that there are very few circulating naive B cells present in peripheral blood and even fewer that possess BCRs specific for any given antigen. Because all B cells constitutively express CD40, the CD40L-induced IgM response circumvents the requirement for antigen specificity and induces a polyclonal B-cell response. Antigen-specific secondary antibody responses are more feasible, especially in response to recall antigens, such as tetanus toxoid. Because a large portion of the human population has undergone repeated and regular vaccination throughout their life (eg, tetanus), HPB B cells possessing BCRs specific for vaccine-associated antigens in these individuals have been clonally expanded and can

be readily activated and quantified *in vitro*. The disadvantage to this approach is that memory B cells, which are the cells that drive the secondary immune responses to recall antigens, have been found to be less sensitive to modulation by immunotoxicants. In light of this, even the CD40L-induced IgM response has been primarily conducted with naive HPB B cells after removal of memory B cells.

Recently, three extensively studied B-cell immunotoxicants in mice, arsenic, benzo[*a*]pyrene-7,8-dihydrodiol-9,10-epoxide (BPDE) and 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) were evaluated using the CD40L-induced IgM AFC response (Lu *et al.*, 2009, 2010). All three immunotoxicants were found to suppress the CD40L-induced IgM AFC response in mouse splenic B cells with the magnitude of suppression being comparable to that previously reported using the sRBC IgM AFC response (Burns *et al.*, 1991; Holsapple *et al.*, 1986; Kawabata and White, 1989). BPDE and TCDD were also found to markedly suppress the CD40L-induced IgM AFC response in HPB B cells, and with a similar magnitude of suppression being observed between mouse and human B cells. In contrast, arsenic did not suppress the CD40L-induced IgM AFC response in HPB B cells. These limited results using only three B-cell immunotoxicants suggest that the mouse may not always serve as a reliable surrogate for predicting immune toxicity in humans.

As will be discussed in the section “The National Toxicology Program Tier Testing Approach,” a cornerstone of immunotoxicological assessments using rodents has been a tier testing battery of immune function assays capable of evaluating the effects of xenobiotics on a host of different immunological parameters. Such an approach has been necessary due to the diversity of cell types and functions that are involved in maintaining immune competence (Luster *et al.*, 1988). In fact, there is strong historical evidence, from examination of the NTP immunotoxicology database, that no immune function assay or endpoint can reliably identify all immunotoxicants. However, if expanded to two or three key assays, a significant increase in concordance with results from the expanded testing battery can be achieved (Luster *et al.*, 1992). Toward this end, it is conceivable that a multiassay approach, analogous to that currently used for evaluations in the mouse, could be employed for immunotoxicity evaluations in conjunction with human primary leukocytes. Until recently, a significant obstacle to such a strategy has been the absence of an *in vitro* assay to assess B-cell effector function (Lu *et al.*, 2009). In fact, a number of immune function assays using primary human leukocytes have historically been widely employed such as the MLR, which provides information on CD4⁺ and CD8⁺ T cell function, in the clinical setting to determine histocompatibility between donors and recipients for tissue transplantation. Similarly, B-cell and T-cell lymphoproliferative responses, which assess lymphocyte clonal expansion, have been used for the past several decades as a preliminary approach to assess human lymphocyte function. Collectively, these assays represent a potential foundation for a human leukocyte immunotoxicology testing battery. As described in the “Biomarkers in Immunotoxicology” section, the development of more predictive biomarkers for the immune system that can provide specific information on the impact of changes in human immunocompetence, and on the susceptibility for disease associated with drug or chemical exposure is another area of intense interest. The possibility of developing better translational biomarkers could facilitate the progression from preclinical studies to clinical studies in drug development.

Regulatory Approaches to the Assessment of Immunotoxicity The maturity and acceptance of any subdiscipline of toxicology can frequently be directly correlated to the

level of interest being demonstrated by the regulatory community. This section will provide a brief review of the history of regulatory approaches to immunotoxicity. It is important to note that the regulatory approaches to immunotoxicity have evolved with the science, and the timing of the introduction of specific guidelines has generally reflected the state-of-the-science. Because of the importance of the evolution of the science, this section will begin with an overview of one of the most comprehensive databases for immunotoxicology.

The National Toxicology Program Tier Approach Although the concept of required immunotoxicity testing is a relatively recent development, the recognition that the immune system is a potential target organ has prompted a consideration of the need to assess the potential of immunotoxicity for some time. All testing strategies to date have recognized the complexity of the immune system as a target organ, and that no single immune parameter can be used with sufficient confidence to test for the hazard of immunotoxicity. Therefore, historically immunotoxicity has been assessed using a battery of assays, which are typically structured in a multi-tiered approach. Importantly, studies conducted by the NTP have indicated that immunotoxicity can be assessed with a finite number of assays. Luster and colleagues (1988) originally described the selection of a battery of tests used by the NTP to screen for potential immunotoxic agents. The result was a tier approach to assessing immunotoxicity, which is summarized in Table 12-10.

Tier I tests provide assessment of general toxicity (eg, immunopathology, hematology, body, and organ weights) as well as some assays to assess immune functional capability (eg, proliferative responses, the T-cell-dependent antibody response assay, measured as AFC, and the NK assay). Tier I was designed to detect potential immunotoxic compounds at concentrations that do not produce overt toxicity. Tier II tests were designed to further define an immunotoxic effect, and included functional tests for CMI (eg, CTL and DTH), secondary antibody responses, enumeration of lymphocyte populations, and host resistance models.

In the original NTP effort, over 50 chemicals were studied, and included a variety of chemical classes, such as catalysts, solvents, dyes, lubricants, pesticides, disinfectants, drugs, food additives, and natural products (Luster *et al.*, 1988). It is important to emphasize

Table 12-10

Tier Approach for Immunotoxicology Testing

TESTING LEVEL	PROCEDURES
Tier I	Hematology Body weight Organ weights (spleen, thymus, kidney, and liver) Spleen cellularity Bone marrow cellularity and CFU Immunopathology AFC assay Proliferative responses NK assay
Tier II	Surface marker analysis Secondary (IgG) AFC assay CTL assay DTH response Host resistance studies

Table 12-11

Suggested Testing Configurations: Three Tests with 100% Concordance

AFC	DHR	Surface markers
AFC	NK	DHR
AFC	NK	Thymus: body weight
AFC	DHR	Thymus: body weight
Surface markers	NK	DHR
Surface markers	DHR	T-cell mitogens
Surface markers	DHR	Thymus: body weight
Surface markers	DHR	LPS response

SOURCE: Luster *et al.* (1988), modified, with permission.

that the chemicals selected for study by the NTP were nominated for testing because of a suspicion that they would target the immune system. These studies were conducted in young adult rodents, principally the mouse, and involved comparative studies across multiple labs. The experimental design emphasized that regardless of the specific immune parameters included in a testing strategy, the interpretation for immunotoxicity could only be made in the context of a well-designed study from the perspective of the dose–response relationship. The approach by Luster and coworkers also emphasized the importance of avoiding high doses (ie, triggered less than a 10% reduction in body weight), because these types of exposures will increase the likelihood that indirect mechanisms of immunotoxicity may be involved.

Several testing configurations were ultimately defined that would minimize the number of immune tests needed, yet could still provide a high degree of sensitivity for detecting potential immunotoxicants. These configurations are depicted in Table 12-11. Specifically, the results indicated that none of the assays measured was 100% predictive alone. The top three assays in terms of detecting immunotoxicants were an assessment of lymphocyte subpopulations by flow cytometric analysis (eg, 83% concordance), the T cell-dependent antibody response (eg, 78% concordance), and an assessment of NK cell activity (eg, 69% concordance) (Luster *et al.*, 1992). With regards to the comparison between the two most sensitive assays, it is important to note that a change in flow cytometric analysis of any of the lymphocyte subsets measured, for example, total B cells, total T cells, CD4⁺ T cells, or CD8⁺ T cells, would be sufficient to establish the concordance of flow cytometry, while the concordance of the T-cell-dependent antibody response was determined solely by the number of AFCs. Subsequent analysis indicated that an application of the full extent of the tiered approach was not necessary. The NTP studies indicated that several combinations of only two tests could give >90% concordance, and that a number of combinations of just three tests gave 100% concordance. In this regard, it is important to note that flow cytometric analysis of lymphocyte subsets, and the T cell-dependent antibody response were consistently involved in both the 2-test concordance of >90%, and in the 3-test concordance of 100%.

Subsequent results also indicated a good correlation between the results from functional tests and host resistance models (Luster *et al.*, 1993), which indicated that the latter were not necessary to adequately identify immunosuppressive potential. The impacts of the NTP database are clear, and one only needs to consider the structure of the immunotoxicity guidelines that have been established to

see the impact of the NTP results. Specifically, after several years of international debate, the importance of including functional immunotoxicity assessments in regulatory studies has been emphasized, as opposed to relying solely on histopathology as an indicator of further testing needs. Moreover, as described further below, the specific immune functional tests in most, if not all, immunotoxicity regulatory guidelines reflect the concordance results described above, and include the T-cell-dependent antibody response, immune cell phenotyping by flow cytometry, and the NK cell assay.

While the original NTP studies in the 1980s were intended to develop and validate methods to evaluate modulation of immune function, the emphasis was clearly focused on immunosuppression. The NTP contract to assess the “Potential for Environmental and Therapeutic Agents to Induce Immunotoxicity” is still assessing chemicals for potential immunomodulation at the rate of four chemicals per year for screening (eg, rangefinding) studies and two chemicals per year for definitive (eg, full protocol) studies. Importantly, the current approaches by the NTP reflect the state-of-the-science of immunotoxicology, in that two developmental immunotoxicity studies, two contact hypersensitivity studies and one study assessing the potential of a xenobiotic-associated change in an autoimmune disease model are assessed each year.

In 2009, the NTP provided another critical component to our understanding of xenobiotic-induced immunotoxicity when they released their “Explanation of Levels of Evidence for Immune System Toxicity” (NTP, 2009) as an approach to judging the quality of results in a study purporting to establish xenobiotic-induced immunotoxicity. In the document, which was prepared by a panel of experts representing the academic, government, and industry sectors of the scientific community, the NTP emphasized the importance of recognizing that the “levels of evidence” statements that are described reflected only immunological *hazard*, and that the actual determination of *risk* to humans required *exposure* data that was not covered in the document. Five categories of evidence of immune system toxicity were used to summarize the strength of the evidence observed in each experiment being considered: two categories for positive results (*clear evidence* and *some evidence*); one category for uncertain findings (*equivocal evidence*); one category for no observable effects (*no evidence*); and one category for experiments that cannot be evaluated because of major design or performance flaws (*inadequate study*). Each category included one or more bullet points for additional clarification. The category for *clear evidence* is worthy of specific mention.

Clear Evidence of Toxicity to the Immune System:

- Is demonstrated by data that indicate a dose-related effect (considering the magnitude of the effect and the dose-response) on more than one functional parameter and/or a disease resistance assay that is not a secondary effect of overt systemic toxicity, or
- Is demonstrated by data that indicate dose-related effects on one functional assay and additional endpoints that indicate biological plausibility. (NTP, 2009)

The significance of this category is that clear evidence of immunotoxicity can be established without the need to conduct a disease resistance assay, and that mechanistic data to establish biological plausibility is weighed very heavily. The NTP report also indicates that negative results, in which the study animals do not exhibit evidence of immunotoxicity, do not necessarily imply that a test article is not an immune system toxicant, but only that the test article is not an immune system toxicant under the specified experimental conditions. Finally, the report indicates that positive results demonstrating that a test article causes immunotoxicity in

laboratory animals under the conditions of the study are assumed to be relevant in humans, unless data are available which demonstrate otherwise.

Historical Perspective on Regulatory Guidance in Immunotoxicology

The history of regulatory guidance in immunotoxicology was reviewed by House (2005). As noted above, the T-cell-dependent antibody response has been the consensus choice for a functional endpoint to identify immunotoxicity hazard in most, if not all regulatory guidelines. A reasonable question to address is what accounts for the sensitivity, predictivity, and (perceived) utility of the T-cell-dependent antibody response. The simplest answer is something that has been known within the immunology community for over 50 years. The T-cell-dependent antibody response requires the orchestrated coordination and cooperativity of multiple cell types (eg, APCs, Th cells, and B cells at the ultimate effector cell because of their ability to secrete antigen-specific antibodies) and the manifestation of most, if not all of the biological functions important to immunocompetence. As noted throughout this chapter, the discipline of immunotoxicology continues to evolve along with advances in immunology and molecular biology. However, in the context of providing an effective screen for immunotoxic hazard, nothing can compare to the time-tested and mechanistically understood specific antibody response to a well-characterized T-dependent antigen.

The Office of Prevention, Pesticides and Toxic Substances (OPPTS) of the US Environmental Protection Agency (EPA) published guidelines entitled, “*Biochemicals Test Guidelines: OPPTS 880.3550 Immunotoxicity*” in 1996. These guidelines described the preferred study design for an exceptionally thorough evaluation of the potential immunotoxicity in biochemical pest control agents. This guideline described a panel of tests that included standard toxicology tests as well as immune functional tests assessing both humoral immunity and CMI. OPPTS 880.3550 clearly presented a very comprehensive approach to immunotoxicity; but a second document, “*Biochemicals Test Guidelines: OPPTS 880.3800 Immune Response*,” was needed to provide the rationale for when these studies should be conducted. The 880 series of immunotoxicity guidelines would arguably detect any type of immunotoxic potential by pesticides. However, the comprehensive nature of these guidelines rendered them prohibitively expensive and time-consuming. The EPA released the “*Health Effects Test Guidelines: OPPTS 870.7800 Immunotoxicity*” in 1998 (EPA, 1998). These guidelines described the approach to immunotoxicology testing for nonbiochemical agents regulated by the EPA. The testing approach in OPPTS 870.7800 reflected the continued evolution of the science of immunotoxicology and called for a more limited, case-by-case approach than previously described by the earlier more comprehensive guidelines. The cornerstone of OPPTS 870-7800 was a functional test, the primary T-cell-dependent antibody response. If the chemical was shown to produce significant suppression of the humoral response, then surface marker assessment by flow cytometry may be performed. If the chemical was not shown to produce suppression of the humoral response, then an assessment of innate immunity (eg, specifically, the NK cell activity assay) may be performed. The specific criteria for the conduct of these “optional” tests have never been identified. The tests do not represent a comprehensive assessment of immune function but are intended to complement assessment made in routine toxicity testing (eg, hematological assessments, lymphoid organ weights, and histopathology).

Internationally, the Organization for Economic Cooperation and Development (OECD) has not as yet adopted specific guidelines for immunotoxicity assessment. As reviewed by House (2005),

the OECD Guideline 407, entitled “*Repeated Dose 28-day Oral Toxicity Study in Rodents*” while not specific for immunotoxicology, includes a variety of toxicological endpoints that can provide early evidence of immune system alterations. House (2005) also noted at the time that over 10 years earlier, an international immunology working group recommended that functional assessments be included in standard toxicology studies when desired or when suggested by expanded histopathological results on other standard toxicology studies. However, to date, the OECD Guideline 407 has not been modified in accord with these recommendations. Moreover, while the OECD published a template for immunotoxicity studies on its website in 2011, there are still no corresponding OECD Test Guidelines for immunotoxicity.

The earliest immunotoxicity guidelines from the Food and Drug Administration (FDA) were centered on food additives as the “*Draft Redbook II*” in 1993. This document, although never finalized, contained an extensive description of immunotoxicology testing. In general, the Redbook guidelines reflected the tiered approach to immunotoxicology (Fig. 12-10), as described in greater detail below. Specifically, the Redbook emphasized a stepwise approach that began with expanded studies utilizing data obtained in standard toxicology testing as initial indicators of immunotoxicity. Progressively more complicated immunological tests were prescribed using an approach that was very much case-by-case, with each new level of testing predicated on positive results in the preceding level. The FDA Center for Drug Evaluation and Research (CDER) released its document entitled, “*Guidance for Industry: Immunotoxicology Evaluation of Investigational New Drugs*,” in 2002 (FDA, 2002). This document is arguably the most comprehensive description of approaches to immunotoxicology. Not only does the FDA CDER “*Guidance for Industry*” describe the full spectrum of adverse events associated with the immunotoxicology continuum including immune suppression, immunogenicity, hypersensitivity, autoimmunity and adverse immune stimulation, but also provides approaches at the level of specific methodology for evaluating each event. As with the earlier document from the FDA, the new “*Guidance for Industry*” advocated the use of information derived from standard repeat-dose toxicity studies to provide the earliest indicators of immunotoxicity. The review by House (2005) also addressed the current status of regulatory guidance for biologicals, vaccines, devices, and radiological agents within the FDA.

Internationally, perhaps one of the most significant advances in our approach to the assessment of immunotoxicity with human pharmaceuticals has been a guidance entitled, “*S8 Immunotoxicity Studies for Human Pharmaceuticals*,” which was prepared under the auspices of the International Conference on Harmonization (ICH) of Technical Requirements for Registration of Pharmaceutical for Human Use (ICH S8, 2006). The objectives of this guideline are twofold: (1) to provide recommendations on nonclinical testing approaches to identify compounds which have the potential for immunotoxicity; and (2) to provide guidance on a weight-of-evidence decision-making approach for immunotoxicity testing. The guidance applies to unintended immune suppression and immune enhancement, excluding allergenicity or drug-specific autoimmunity. The ICH S8 guideline is based on a cause for concern approach using a review of factors such as the following: results from Standard Toxicity Studies (STS), pharmacological properties of the drug, the intended patient population, structural similarities to known immune modulators, the disposition of the drug, and clinical information.

As emphasized in the Introduction, immunotoxicity exists in a continuum (Fig. 12-1). By and large, more effort has been invested in the validation of studies to address the immunosuppressive part

of the continuum, and there is no doubt that much attention is paid to immune suppression in the majority of guidance documents (House, 2005). Nonetheless, it is important to measure xenobiotic-induced changes in immune function in both directions. As noted by House (2005), it is hypersensitivity that is the most common type of immune modulation in humans resulting from exposure to xenobiotics. One of the most significant advances in our approach to assessing the potential of xenobiotics has been the LLNA. As discussed above, the LLNA was the first assay to be evaluated by the Interagency Coordinating Committee for the Validation of Alternative Methods (ICCVAM). The impact of this decision by ICCVAM is that the LLNA is now an accepted assay and discussed in considerable detail in the OECD 429 Guideline, “*Skin Sensitization: Local Lymph Node Assay*,” and the EPA document, “*OPPTS 870.2600 Skin Sensitization*.”

Recent Advances in Regulatory Guidance on Immunotoxicology

There have been two areas over the last few years that have impacted the status of immunotoxicology testing which are either legislative demands or because of the continued evolution in the state-of-the-science.

As noted in the sections above on “Molecular Biology Approaches to Immunotoxicology” and “Mechanistic Approaches to Immunotoxicology”, the use of in vitro and cell-based tissue culture methods have always played an important role in the science of immunotoxicology. Of course, it has always been recognized that the use of these alternative approaches are consistent with the 3Rs of reducing, replacing, and refining the use of whole animal studies. However, recent legislative actions, such as the implementation of Registration, Evaluation and Authorization of Chemicals (REACH) and of the Cosmetics Directive in Europe, have focused renewed and required attention on in vitro approaches to all types of toxicity assessment, including immunotoxicity, especially in Europe (Carfi *et al.*, 2007; Galbiati *et al.*, 2010; Lankveld *et al.*, 2010). Some recent specific examples of the utility of in vitro approaches to assess immunotoxicity include an improved in vitro cytokine release using human PBMC (Kooijman *et al.*, 2010), and some renewed interest (Fischer *et al.*, 2011) in the Mishell–Dutton culture system (Mishell and Dutton, 1967) that was described earlier in the subsection “General Assessment” under the “Methods to Assess Immunocompetence” section. Not too surprisingly, Fischer *et al.* (2011) conclude that the investigation of in vitro antibody responses is a sensitive and reliable approach for the detection of a compound-specific effect on the immune system. They also conclude that the implementation of this approach in routine toxicology would enable the refinement of existing in vivo studies by reducing the number of animals. However, somewhat surprising is their conclusion that the in vitro Mishell–Dutton culture system for measuring specific antibody responses of primary cells may replace the ex vivo T-cell-dependent antibody response in the future. A significant concern pertaining to the utilization of this strictly in vitro approach is that leukocytes possess remarkably limited drug-metabolizing capability and as such, agents that are activated by metabolism to an immunotoxic form would not be detected utilizing this strategy.

As described in another section of this chapter, the interest in DIT testing has increased significantly over the last few years, with considerable attention being devoted to this area of study by the scientific and regulatory communities on a global scale. While it is important to emphasize that there are currently no regulatory guidelines for either drugs or nondrug chemicals specifically focused on assessment of DIT, but there are some general guidelines included in both developmental and reproductive toxicity (DART) and general immunotoxicology guidance documents. Evaluations of DIT began

to be required as part of the US Environmental Protection Agency's Office of Prevention, Pesticide and Toxic Substances (OPPTS) test guideline for the 2-generation reproductive toxicity study (EPA, 1998), which requires collection of spleen and thymus weights in one pup per sex per litter in F_1 and F_2 weanlings. Another example of this trend in the context of assessing the effects of chemicals on the developing immune system is the paper by Cooper *et al.* (2006), in which the authors described an expanded one-generation DART protocol that included the assessment of immunotoxicology—among other endpoints—following exposure during critical windows of development. More recently, Vogel *et al.* (2010) described a modular one-generation reproduction study—that included an immunotoxicity module—as a flexible testing system for regulatory safety assessment, and highlighted the application of such an approach to the EUs REACH program. Based on these kinds of proposed studies, the US EPA and the Dutch authorities convened a working group to revise the OECD 415 protocol to embrace some of the principles articulated by Cooper *et al.* (2006) and by Vogel *et al.* (2010). Indeed, in 2010, the OECD released a draft protocol for a revised OECD 415, extended one-generation study (OECD, 2010) that included three cohorts, with the third cohort devoted to an assessment of the potential impact of chemical exposure on developmental immunotoxicity.

In its 2002 guidance for industry, FDA noted that all drugs that are immunotoxic in adult animals and are to be given to pregnant women should be evaluated for DIT (FDA, 2002). Endpoints recommended to be assessed were hematology and lymphoid organ weights on F_1 pups in standard DART studies. More recently, a number of regulatory guidelines have also emerged to address the safety of drugs intended for pediatric indications, including the US FDA *Guidance for Industry Nonclinical Safety Evaluation of Pediatric Drug Products* (FDA, 2006; Tassinari *et al.*, 2011), and the European Medicines Agency *Guideline on the Need for Nonclinical Testing in Juvenile Animals on Human Pharmaceuticals for Paediatric Indications* (Carleer and Karres, 2011; EMA, 2008). In Japan, the Ministry of Health, Labor, and Welfare (MHLW) started to prepare their *Guideline for Nonclinical Safety Studies in Juvenile Animals* in 2010 (Shimomura, 2011). In general, juvenile toxicity studies are conducted to identify potential latent signs of toxicity, to characterize the potential for chronic developmental toxicity that cannot be thoroughly assessed through standard DART protocols, and to ensure that children are not unnecessarily exposed to potentially adverse risk factors. The primary objective of juvenile animal toxicity studies of pharmaceuticals is to obtain safety data, including information on the potential for adverse effects on postnatal growth and development (Capon *et al.*, 2009). Indeed, the FDA Guidance from their CDER addresses "...the role and timing of animal studies in the safety evaluation of therapeutics intended for the treatment of pediatric patients," and emphasizes the following premise, "It is thought that organ systems at highest risk for drug toxicity are those that undergo significant postnatal development" (FDA, 2006). Importantly, the immune system was identified in the FDA Guidance as an important endpoint.

While the revised OECD 415 protocol described above has been designed to assess the effects of chemical exposure in rats, more recently, evaluations of DIT for pharmaceuticals in non-human primates have been conducted as part of embryofetal development (EFD), pre-/postnatal development (PPND), or juvenile studies. With regard to critical immune system "windows," the enhanced PPND (ePPND) study design in non-human primates (NHPs) appears optimal for DIT testing, and has been shown to have similar benefits to the testing of monoclonal antibodies (Stewart, 2009) and biopharmaceuticals (Martin *et al.*, 2009). Additional perspective on

the state-of-the-science of juvenile immunotoxicology studies for pharmaceuticals is provided in a paper by Holsapple and O'Lone (2011).

Biomarkers in Immunotoxicology There are many potential definitions for a "biomarker." From a toxicological perspective, the most general definition of a biomarker is a substance that can be measured in a biological system or sample that reflects a xenobiotic-induced change in cellular or biochemical components or processes, structures, or function. From a clinical perspective, a biomarker is a term often used to refer to something that can be measured whose concentration reflects the severity or presence of some disease state. As such "true" biomarkers indicate exposure to a specific chemical or drug as well as susceptibility to an adverse effect, and/or are predictive of changes in a disease state associated with chemical or drug exposure. Although traditionally biomarkers are most often associated with proteins that can be measured in the blood, biomarkers can also be associated with changes in the expression of cell-surface proteins, and, in the new world of "omics" technologies, biomarkers can not only be identified through proteomics; but through transcriptomics and metabolomics (metabonomics), as well. Translational biomarkers are those that can be effectively used in multiple species, and that can be used to bridge the effects seen in two different species so that it would be possible to directly link responses between species. In the context of drug development, translational biomarkers that can be measured in both humans and non-human species are critical so that effects seen with a drug candidate can be followed in both preclinical and clinical settings.

Based on an understanding of the immune system, especially in the context of any type of immune response, it is easy to see the potential for biomarkers in immunotoxicology. Essentially, any xenobiotic-induced change in any parameter associated with an immune response—for example, a change in an antigen-specific antibody response, or a change in the expression of a surface marker, or a change in the numbers of a particular immune cell type, or a change in the levels of a cytokine or cytokines, or a change in the expression of an immune response-related gene—could be used as a biomarker for the immunotoxicity associated with that xenobiotic. As such, a chapter entitled, "The Promise of Genomics and Proteomics in Immunotoxicology and Immunopharmacology" (Pruett *et al.*, 2007), emphasized that further implementation of these methods could move immunotoxicology into the area of systems biology, could be beneficial with regard to mechanistic and screening applications, and could reveal new insights about immune function. Similarly, an earlier report by the National Research Council's Committee on Biological Markers undertook to study the interrelationship of toxic exposure and immune system response at a time when the discipline of immunotoxicology was described as being "relatively young"—for example, the IL family ended with IL-8 (NRC, 1992). The NRC Subcommittee on Immunotoxicology reviewed research on currently known markers, and identified and evaluated promising technologies to find new markers.

In spite of this early effort by the NRC, and although the NTP Tier Approach for assessing whether a compound is immunotoxic has been used for many years and has served as the basis for most immunotoxicity regulatory guidelines, there is no consensus for an accepted panel of biomarkers that one can use to determine whether, and to what extent, exposure to an immunotoxic agent has occurred. Various studies have been conducted to ascertain the feasibility, predictability, and accuracy of various biomarkers of immune modulation (Karmaus *et al.*, 2005; Luster *et al.*, 2005; Schwab *et al.*, 2005). Besides the potential biomarkers already mentioned, which include

cytokine gene expression patterns, cell population quantification using flow cytometry, and serum antibody titers, the assessment for the presence of single nucleotide polymorphisms (SNPs) in various genes makes it possible to determine whether small populations of individuals might be more susceptible to immunotoxicants. These same approaches are being applied to the development of immunomodulators and biologics, which are either designed to target the immune system, or are likely to do so because of their mechanisms of action. As such, it is more critical than ever that translational biomarkers for the immune system be developed and tested.

Finally, while it is clear from a number of studies currently available that biomarkers for the immune system can be predictive and accurate, there are limitations of their use, especially in the context of their application in human epidemiological studies. For example, suppression of CD4⁺ T cells certainly indicates immune suppression, but it would be challenging to determine which agent(s) correlate with the magnitude of suppression, and how the exposure to multiple agents affects that magnitude. Moreover, it should be noted that immunological biomarkers might be affected by other physiological processes, such as stress (Schwab *et al.*, 2005); and as described in the preceding subsection, “Approaches to the Assessment of Human Immunotoxicity,” stress can affect immune responses to vaccines in humans (Glaser *et al.*, 2000; Kiecolt-Glaser *et al.*, 1996). Certainly, the complex interplay between different physiological processes is not unique to immunotoxicology; but it will need to be considered as the concept of biomarkers in immunotoxicology is developed.

IMMUNE MODULATION BY XENOBIOTICS

The very nature of the immune system with the different cell types, the presence of various cell types in every tissue of the body, the dependence on proliferation and differentiation for effector functions, and the necessity to maintain immune function homeostasis renders it susceptible to modulation by a wide variety of xenobiotics. Although many of the xenobiotics discussed below exhibit immunosuppressive actions, it is important to realize that many of these chemicals are actually immunomodulatory, that is, they might produce both immune suppression and immune enhancement (in the absence of true hypersensitivity or autoimmunity). Of course, one cannot ignore the chemicals that do produce true hypersensitivity and/or autoimmunity and some examples of these are discussed later in the section entitled, “Xenobiotic-Induced Hypersensitivity and Autoimmunity.” Regardless of the end effect (immune suppression, immune enhancement, hypersensitivity, or autoimmunity) of a particular xenobiotic on the immune system, several common themes exist regarding the mechanisms by which these chemicals act. First, the mechanisms by which a xenobiotic affects immune function are likely to be multifaceted, involving several proteins, signaling cascades, or receptors. In fact, for several of the xenobiotics discussed below, there is evidence to suggest that immune system effects are both xenobiotic-specific receptor-dependent and -independent. Second, whether a xenobiotic produces a particular immune effect might depend on the concentration or dose of the xenobiotic, the mode and/or magnitude of cellular stimulation, and the kinetic relationship between exposure to the xenobiotic and exposure to the immune stimulant (ie, antigen, mitogen, and pharmacological agent). Third, xenobiotic exposures rarely occur one chemical at a time; thus, the effects and/or mechanisms observed might be attributable to several chemicals or classes of chemicals. Finally, determination of immune system effects and/or mechanisms by xenobiotics in humans might be further confounded by the physiological or immunological state of the individual. Despite

these variables, the application of general, functional, and mechanistic tools discussed above have driven the determination of some of the effects and mechanisms for several xenobiotics.

Halogenated Aromatic Hydrocarbons

Few classes of xenobiotics have been as extensively studied for immunotoxicity as the halogenated aromatic hydrocarbons (HAHs); reviewed by Holsapple, 1996; Kerkvliet, 2002; Kerkvliet and Burleson, 1994). The prototypical and most biologically potent member of this family of chemicals, which includes the polychlorinated biphenyls (PCBs), the polybrominated biphenyls (PBBs), the polychlorinated dibenzofurans (PCDFs), and the polychlorinated dibenzodioxins (PCDDs), is 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD; dioxin). Substantial evidence has demonstrated that the immune system is a sensitive target for toxicity by these chemicals. Derived from a variety of animal models, primarily rodents, this evidence includes thymic atrophy, pancytopenia, cachexia, immune suppression, and tumor promotion. There is also epidemiological evidence suggesting that immunotoxicity by the HAHs can also occur in humans (Weisglas-Kuperus *et al.*, 1995, 2000, and 2004); however, significant immune suppression has not been associated conclusively with specific alterations of human immune function.

The majority of the biochemical and toxic effects produced by the HAHs are mediated via HAH binding to the cytosolic AHR. The AHR is a 95 to 110 kDa basic helix-loop-helix type of ligand-activated transcription factor (Burbach *et al.*, 1992; Ema *et al.*, 1992), which is associated with two heat shock proteins (hsp90) (Denis *et al.*, 1988; Perdew, 1988; Pongratz *et al.*, 1992), prostaglandin E synthase 3 (p23) (Cox and Miller, 2004; Kazlauskas *et al.*, 1999) and AHR-activated 9 (ARA-9) (Carver *et al.*, 1998; LaPres *et al.*, 2000; Ma and Whitlock, 1997). Ligand binding induces conformational changes in the AHR, enabling the receptor-ligand complex to initially release p23 and ARA9 in the cytosol followed by nuclear translocation where it sheds its hsp90 and is transformed into a DNA-binding protein (Cuthill *et al.*, 1987; Denis *et al.*, 1988; Okey *et al.*, 1980; Perdew, 1988; Pollenz *et al.*, 1994; Pongratz *et al.*, 1992; Probst *et al.*, 1993). This transformation involves dimerization of the receptor-ligand complex with a structurally related 87 kDa basic helix-loop-helix protein termed the aryl hydrocarbon receptor nuclear translocator (ARNT) (Hoffman *et al.*, 1991; Probst *et al.*, 1993; Reyes *et al.*, 1992). The ligand-AHR/ARNT complex acts as a transcription factor by binding to DNA at the dioxin-responsive element (DRE), also termed xenobiotic response elements (XRE), in the promoter and enhancer region of sensitive genes such as cytochrome P4501A1, aldehyde dehydrogenase-3, glutathione *S*-transferase, and menadione oxidoreductase (Dunn *et al.*, 1988; Elferink *et al.*, 1990; Fujisawa-Sehara *et al.*, 1987; Hoffman *et al.*, 1991; Poland and Knutson, 1982; Reyes *et al.*, 1992; Sutter and Greenlee, 1992; Watson and Hankinson, 1992; Whitlock, 1990). Numerous lines of evidence have supported the involvement of the AHR in mediation of toxicity including immunotoxicity by HAHs. Structure-activity relationship studies have demonstrated that with few exceptions, high-affinity AHR ligands are more immunosuppressive than low-affinity ligands (Davis and Safe, 1988). In mice, allelic variation at the *Ah* locus has been described. These alleles code for AHR with differential binding affinities for TCDD. For example, the C57BL/6 mouse represents a strain of mice (*Ah^{bb}*), which is exquisitely sensitive to TCDD (TCDD responsive), while the DBA/2 mouse strain (*Ah^{dd}*) is much less sensitive to the toxic effects of TCDD (TCDD nonresponsive or TCDD low-responsive). More recently, AHR null mice and cell

lines that do not express the AHR have collectively provided compelling evidence supporting the role of AHR in the toxicity mediated by HAHs including immunotoxicity (Sulentic *et al.*, 2000; Vorderstrasse *et al.*, 2001).

Polychlorinated Dibenzodioxins By far the majority of the investigations into the immunotoxic potential and mechanisms of action of the HAHs have focused on TCDD, primarily because this chemical is the most potent of the HAHs, binding the AHR with the highest affinity. The effects of TCDD on immune function have been demonstrated to be among the earliest and most sensitive indicators of TCDD-induced toxicity (reviewed by Holsapple, 1996; Holsapple *et al.*, 1991a, b; Kerkvliet, 2002; Kerkvliet and Burleson, 1994). TCDD is not produced commercially, except in small amounts for research purposes. Rather, it is an environmental contaminant formed primarily as a by-product of the manufacturing process that uses chlorinated phenols or during the combustion of chlorinated materials. It is usually associated with the production of herbicides such as 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), and Agent Orange (a 1:1 combination of 2,4-dichlorophenoxyacetic acid [2,4-D] and 2,4,5-T). Other sources include pulp and paper manufacturing (chlorine bleaching), automobile exhaust (leaded gasoline), combustion of municipal and industrial waste, and the production of PCBs.

Like other HAHs, exposure to TCDD results in severe lymphoid atrophy. Because thymus-derived cells play an integral role in tumor surveillance and host resistance, the earliest studies on TCDD-induced immunotoxicity focused on changes in CMI. Studies on CMI have shown that this branch of acquired immunity is sensitive to the toxic effects of TCDD after *in vivo* administration. CTL development and activity have been shown by numerous investigators to be significantly decreased after exposure to TCDD, an effect that appeared to be age dependent (eg, the younger the mice when exposed, the greater the sensitivity to TCDD). In an *in vivo* acute graft-versus-host model of T-cell immunity, the direct AHR-dependent effects of TCDD on T cells were demonstrated. In this model, T cells from C57BL/6 mice were injected into C57BL/6 × DBA/2 F1 host mice resulting in the generation of an antihost CTL response (Kerkvliet *et al.*, 2002). By comparing the ability of TCDD to suppress the CTL response of T cells obtained from AHR^{+/+} and AHR^{-/-} C57BL/6 mice, the role for AHR expression in T cells was assessed. These studies showed that the CTL response was suppressed by TCDD through direct effects on CD4⁺ and CD8⁺ T cells via an AHR-dependent mechanism (Kerkvliet *et al.*, 2002). The findings are consistent with the identification of AHR expression in T cells (Lawrence *et al.*, 1996) and structure-activity relationship studies showing a positive correlation between AHR-binding affinity of dioxin-like PCBs and suppression of *in vivo* CTL responses (Kerkvliet *et al.*, 1990). More recently using the same graft-versus-host model, TCDD treatment resulted in a significant increase in the percentage of donor CD4⁺ cells that expressed high levels of CD25, low levels of CD62L as well as glucocorticoid-induced TNFR (GITR) and CTLA-4, a phenotype associated with some types of Tregs, suggesting that an important component of the immune suppression of the CTL response induced by TCDD might be the generation of Tregs (Funatake *et al.*, 2005). In addition to suppression of CTL function, TCDD exposure also results in decreases in PHA- and Con A-induced proliferative responses, and DTH responses. Enhanced proliferative responses in juvenile mice have also been observed (Lundberg *et al.*, 1990). Concordant with the aforementioned findings, more recently it has been reported that AHR activation by TCDD or by the tryptophan-derived endogenous AHR ligand, 2-(1^H-indole-3[']-carbonyl)-thiazole-4-carboxylic

acid methyl ester, induced the generation of Tregs in a model of experimental autoimmune encephalomyelitis (EAE), which produced a reduction in severity of disease (Quintana *et al.*, 2008). These findings are somewhat in contrast to the observation that 6-formylindolo[3,2-*b*]carbazole, also a tryptophan-derived high-affinity AHR ligand, induced IL-17 production by Th17 cells and increased the severity of disease in the same EAE autoimmune model (Quintana *et al.*, 2008; Veldhoen *et al.*, 2008). Importantly, Th17 cells and Tregs negatively cross regulate each other, and this observation raises what appears to be a dichotomy in that AHR activation in the same model of autoimmunity can produce very different outcomes and may be in part explained by the ligand which activates the AHR. Moreover, transcriptome analysis showed that of four types of CD4⁺ T cells (Th1, Th2, Tregs, and Th17 cells), AHR was only detected in Th17 cells suggesting that some of the effects produced by TCDD and dioxin-like compounds on T cells may occur indirectly (Veldhoen *et al.*, 2008).

In light of the critical role DCs play in regulating T-cell-mediated responses by presenting antigen to CD4⁺ and CD8⁺ T cells as well as by providing costimulatory signals through surface expression of CD80 and CD86 to drive T-cell activation via CD28 (T-cell coreceptor), recent investigations have focused on characterizing the effects TCDD exerts on DC function. Indeed, differentiation of bone marrow-derived precursors into DCs in the presence of TCDD was found to influence the expression of several surface proteins on DCs known to play a critical role in T-cell antigen recognition and T-cell activation. Specifically, differentiation of bone marrow precursors in the presence of TCDD resulted in an increase in MHCII, CD80, and CD86 expression, when compared to vehicle controls (Bankoti *et al.*, 2010; Simones and Shepherd, 2011), which occurred in an AHR-dependent manner. Interestingly, in spite of the dependence on the AHR these changes were not dependent on AHR-mediated changes in gene expression since DCs from mice possessing a mutation within the AHR nuclear localization signaling domain exhibited a similar profile of activity as those derived from wild-type mice. While significant TCDD-mediated increases in MHCII, CD80, and CD86 expression were observed, TCDD-treated DCs exhibited a similar capacity as vehicle-treated DCs to activate CD8⁺ T cells, which would suggest that TCDD-mediated suppression of CTL responses does not involve altered DC function. In contrast, DCs differentiated in the presence of TCDD exhibited suppressed levels of TNF- α , IL-6, and IL-12 in response to TLR-mediated (LPS or CpG) activation suggesting altered cytokine regulation (Simones and Shepherd, 2011).

Consistent with the observation that mice exposed perinatally or postnatally are more sensitive to the effects of TCDD, it has been determined that thymic involution is a result of TCDD-induced terminal differentiation of the thymic epithelium and, thus, T cells do not have a proper nutrient-filled microenvironment in which to develop (Greenlee *et al.*, 1984, 1985). This conclusion is consistent with observations that TCDD significantly decreased the number of immature T cells (CD4⁺/CD8⁺) in the thymus (Kerkvliet and Brauner, 1990). It was also reported that *in vivo* administration of TCDD-induced apoptosis in mouse thymocytes (Kamath *et al.*, 1999) and that the mechanism involved a TCDD-induced increase in Fas ligand in thymic stromal, but not thymic, T cells (Camacho *et al.*, 2005). In these experiments, it was demonstrated that when TCDD-exposed stromal cells were mixed with untreated thymic T cells, increased apoptosis was detected in T cells that involved Fas-Fas ligand interactions. In addition, the TCDD-mediated apoptosis of thymic T cells was demonstrated to occur via an AHR-dependent mechanism, which also involved NF- κ B-mediated upregulation of Fas ligand promoter activity in the thymic stromal cells (Camacho

et al., 2005). It has also been shown that TCDD interferes with cell-cycle regulation during early thymocyte development, which may in part account for the profound sensitivity of thymocytes to AHR ligands (Laiosa *et al.*, 2003). More recently, differential TCDD-induced gene expression was observed during different stages of thymocyte development providing new insights into putative targets responsible for altered thymocyte differentiation in the presence of TCDD. Interestingly, this study also revealed that the cell cycle was unaffected at the earliest stages of thymocyte development prior to commitment to the $\alpha\beta$ T-cell lineage (Laiosa *et al.*, 2010).

Numerous investigations have demonstrated humoral immunity, and in particular, the IgM AFC response, to be exquisitely sensitive to the toxic effects of TCDD (Sulentic and Kaminski, 2011). This effect segregates with the *Ah* locus (Sulentic *et al.*, 2000; Vecchi *et al.*, 1983) and appears to be dependent on duration and conditions of exposure. Although TCDD induces profound changes in the AFC assay, no changes have been observed in splenic cellularity (numbers of Ig⁺, CD4⁺, or Thy-1⁺ cells) either before or after antigen challenge. Cell fraction/reconstitution of splenocytes from in vivo TCDD and/or vehicle-treated mice identify the B cell as the primary cell type impaired in the AFC response, with only modest changes observed in T-cell accessory function (Dooley and Holsapple, 1988). Interestingly, unlike CMI-mediated responses, which were only affected when TCDD treatment was performed in vivo, direct addition of TCDD to leukocyte cultures was found to strongly suppress humoral immune responses to a variety of B-cell antigens and activators (ie, LPS, dinitrophenyl-ficoll, and sRBC) demonstrating the ability of TCDD to directly target B cells (Holsapple *et al.*, 1986). Investigations using AHR null mice and cell lines that differentially express AHR have demonstrated definitively that suppression of primary humoral immune responses by TCDD is dependent on AHR activation (Sulentic *et al.*, 2000; Vorderstrasse *et al.*, 2001). More recently, motif searches of regulatory regions of genes involved in controlling Ig expression led to the identification of DREs in a transcriptional regulatory region (termed 3'*IghRR*) of the Ig heavy chain gene. The 3'*IghRR* plays a crucial role in mediating high-level Ig heavy chain expression and Ig class switching. Electrophoretic mobility shift assays identified TCDD-induced AHR DNA binding, and transient transfection experiments demonstrated strong suppression of 3'*IghRR* reporter activity by TCDD in a cell line model of B-cell differentiation (Henseler *et al.*, 2009; Sulentic *et al.*, 2000, 2004a, b). However, suppression of humoral immune responses by TCDD cannot be completely reconciled by altered regulation of the 3'*IghRR* and the Ig heavy chain as TCDD-treatment also significantly suppresses expression of the Ig light chain and Ig J chain (Yoo *et al.*, 2004). Additional studies revealed that a bistable biological switch controlling B cell to plasma cell differentiation as formed by the transcriptional repressors, B-cell lymphoma-6 protein (BCL-6), B lymphocyte-induced maturation protein-1 (Blimp-1), and paired box protein 5 (Pax5) is significantly altered in the presence of TCDD (Bhattacharya *et al.*, 2010; Zhang *et al.*, 2010) resulting in elevated levels of Pax5 due to repression of Blimp-1 (North *et al.*, 2009; Schneider *et al.*, 2008, 2009). Importantly, Pax5 is highly expressed in resting B cells simultaneously repressing the Ig heavy chain, light chain, and J chain and is in turn repressed by Blimp-1 to allow plasma cell differentiation and Ig production. Deregulation of this bifunctional switch by TCDD is mediated in part through decreased AP-1 DNA binding within the Blimp-1 promoter (Schneider *et al.*, 2009) in combination with direct AHR-mediated induction of Bach2 (De Abrew *et al.*, 2011), which acts as a repressor of Blimp-1. Collectively, the aforementioned findings suggest that humoral immune responses are suppressed through the direct actions of TCDD on B cells via a

AHR-dependent mechanism through multiple related, but distinct, mechanisms acting in concert which include but are likely not limited to: (1) direct action of the AHR on the 3'*IghRR* of the Ig heavy chain; (2) deregulation of a bifunctional switch controlling B-cell differentiation resulting in elevated Pax5 and repression of the Ig heavy chain, light chain, and J chain; and (3) impaired B-cell activation (North *et al.*, 2010).

The effects of TCDD on innate immunity are less well studied. TCDD has been shown to suppress some functions of neutrophils, including cytolytic and cytostatic activities. This suppression has been postulated as being related to neutrophil development in the bone marrow. Results by several investigators have shown TCDD-induced alterations in serum C3, indicating that soluble mediators of innate immunity may also be targeted (White and Anderson, 1985; White *et al.*, 1986). There have been no observed effects on macrophage-mediated cytotoxicity, NK function, or IFN production. In host resistance models, TCDD exposure has been shown to increase susceptibility to several bacterial, viral, and tumor models. The most extensively employed model of host resistance for assessing the effects of TCDD on immune competence has been influenza virus. Uniformly, all of these studies have shown impaired resistance to influenza after TCDD treatment as evidenced typically by increased mortality (Burlison *et al.*, 1996; Nohara *et al.*, 2002; Warren *et al.*, 2000). However, it is noteworthy that significant differences have been reported between laboratories concerning the magnitude of impairment produced by TCDD, which may be due in part to differences in the strain of influenza virus used. In this model of host resistance, lymphocyte migration to the lung and the production of virus-specific IgG_{2a}, IgG₁, and IgG_{2b} antibodies were markedly diminished while IgA and neutrophilia were increased in TCDD-treated mice (Vorderstrasse *et al.*, 2003). Conversely, in this same study, no significant TCDD-associated effects were found on T-cell expansion in the lymph nodes and on the production of IFN- γ and IL-12. Collectively, the results suggested that the increase in mortality to influenza in TCDD-treated mice was due to decreased antibody production and increased pulmonary inflammation (Vorderstrasse *et al.*, 2003).

TCDD has also been identified as a potent immunohematopoietic toxicant with the ability to alter the number of Lin-Sca-1⁺cKit⁺ (LSK) bone marrow cells, a population enriched for murine HSCs. Assessment of bone marrow cells from TCDD-treated C57BL/6J mice for hematopoietic alterations revealed increases in the number of bone marrow LSK cells, relative to control, over 24 hours through 31 days following TCDD treatment. These findings suggest that proliferation and/or differentiation processes of HSCs are affected by TCDD and that these effects contribute to a reduced capacity of bone marrow to generate pro-T lymphocytes (Murante and Gasiewicz, 2000). Activation of the AHR by TCDD was also found to elicit disruptions in the circadian rhythms of hematopoietic precursors as evidenced by an abnormal in vivo rhythm of the percentage of the total number of LSK cells in G₀ phase of the cell cycle, suggesting disruption of stem cell quiescence (Garrett and Gasiewicz, 2006). In addition, expression of AHR and ARNT mRNA within enriched hematopoietic precursors oscillated with a circadian period. Taken together, these findings demonstrate that activation of the AHR by TCDD alters the profile of hematopoietic precursors as well as the circadian rhythms associated with these precursors.

There is little doubt that TCDD and related PCDDs are immunotoxic, particularly in mice. However, extrapolation to human exposure has proven to be difficult. There are a few instances in which accidental human exposure to TCDD and related congeners has afforded the opportunity to study exposure-related human

immunological responses. In children exposed to PCDDs in Seveso, Italy (1976), nearly half of the exposed study group exhibited chloracne (a hallmark of high-level human exposure to PCDDs) three years after the accident. Immune parameters measured at that time were unaffected. In a second study conducted six years later on different subjects, there was an increase in complement, which correlated with the incidence of chloracne, an increase in circulating T and B cells, and an increase in PBMC mitogenic responses. In 2002, follow-up studies in which the population in the most highly exposed zone was randomly sampled, revealed modestly decreased median serum IgG but not IgM, IgA, C3, and C4 concentrations as compared to human subjects in the surrounding noncontaminated area (Baccarelli *et al.*, 2002). A second incident occurred in 1971 in Times Beach, Missouri, when wastes containing TCDD were sprayed on roads to prevent dust formation. Both low-risk and high-risk individuals from this area were examined for DTH responses. Slight, but statistically nonsignificant alterations were observed in high-risk compared to low-risk individuals. In addition, there was a low-level increase in mitogenic responsiveness in high-risk persons. In a second study conducted 12 years later, no alterations were observed in DTH or mitogenic responses between exposed or control individuals. In studies undertaken to evaluate the *in vitro* effects of TCDD on human cells, TCDD suppressed IgM secretion by human B cells in response to the superantigen toxic shock syndrome toxin-1 and the proliferation and IgG secretion of human tonsillar B cells in response to LPS and cytokines (Wood and Holsapple, 1993; Wood *et al.*, 1993). More recently, employing an *in vitro* CD40L B-cell activation model, HPB B cells were found to possess similar sensitivity to TCDD, as quantified by suppression of IgM AFC response, as mouse B cells expressing the high-affinity form of the AHR (C57BL/6) (Lu *et al.*, 2010). In addition, HPB B cells also showed a marked impairment in the upregulation of activation markers, CD80, CD86, and CD69, and rapid attenuation (15–30 minutes postactivation) of protein phosphokinases including Akt as well as the mitogen-activated protein kinase, ERK, in the presence of TCDD (Lu *et al.*, 2011). The impairment of CD80 and CD86 by TCDD on HPB B cells is in contrast to the increased upregulation of CD80 and CD86 by TCDD on mouse bone marrow DC discussed above (Bankoti *et al.*, 2010; Simones and Shepherd, 2011) and may reflect species and/or cell-type related differences in the actions of TCDD within the immune system. Collectively, these results suggest that human B cells are sensitive to suppression by TCDD. Moreover, the effects of TCDD on human B cells are direct and involve, at least in part, attenuation of early B-cell activation events, which culminate in impairment of plasma cell formation. These results further suggest that TCDD-mediated suppression of B-cell function, although AHR-dependent, likely involves transcriptional as well as nontranscriptional mechanisms.

Polychlorinated Dibenzofurans Like the PCDDs, polychlorinated dibenzofurans (PCDFs) are not produced commercially but are true environmental contaminants associated with the production of chlorophenoxy acids, pentachlorophenol, and other PCB mixtures. Although higher concentrations are required to achieve observable effects, the immunotoxic profile of the PCDFs is similar in nature to that described for TCDD. In fact, most of what is known regarding the immunotoxicity of the PCDFs in animal models has been learned with structure–activity relationship studies comparing TCDD to congeners of the dibenzofurans. Tetrachlorodibenzofuran (TCDF) exposure in most species is associated with thymic atrophy and, in guinea pigs, it has been shown to suppress the DTH and lymphoproliferative responses to PHA and LPS. Suppression of the AFC response to SRBC after exposure to several PCDF

congeners has also been reported. In a more recent study of simple mixtures, dose–response studies comparing TCDD to either a mixture of PCDDs and PCDFs or to a mixture of PCDFs, PCDDs, and PCBs showed that each of the two mixtures produces strikingly similar suppression of the mouse *in vivo* anti-sRBC IgM AFC responses as TCDD alone when normalized to the total TCDD equivalents administered (Smialowicz *et al.*, 2008). It is noteworthy that although the immunotoxicology database is extensive for TCDD and other PCDDs, it remains limited for PCDFs.

Two important case studies of human immunotoxicology involved populations accidentally exposed to HAHs. There is evidence that the PCDFs were the primary contributors to the observed toxic effects. Greater than 1850 individuals in Japan (in 1968) and in excess of 2000 people in Taiwan (in 1979) were affected when commercial rice oil was found to be contaminated with HAHs. PCDFs were observed in the tissues of the exposed populations, and subsequent studies on immune status revealed a decrease in total circulating T cells, decreased DTH response, and enhanced lymphoproliferative responses to PHA and pokeweed mitogen. In addition, many of the exposed individuals suffered from recurring respiratory infections, suggesting that host resistance mechanisms had been compromised.

Polychlorinated Biphenyls PCBs have seen extensive commercial use for over half a century. Their unique physical and chemical properties make PCB mixtures ideal for use as plasticizers, adhesives, and as dielectric fluids in capacitors and transformers. Mixtures of PCBs (eg, Aroclors) have been commonly used to evaluate the immunotoxicity of PCBs and have been reported to suppress immune responses and decrease host resistance (reviewed by Holsapple, 1996). The first indication that PCBs produced immunotoxic effects was the observation of severe atrophy of the primary and secondary lymphoid organs in general toxicity tests and the subsequent demonstration of the reduction in numbers of circulating lymphocytes. Studies to characterize the immunotoxic action of the PCBs have primarily focused on the antibody response. This parameter is by far the one most consistently affected by PCB exposure, and effects on antibody response have been demonstrated in guinea pigs, rabbits, mice, and rhesus monkeys. PCB-exposed monkeys exhibit chloracne, alopecia, and facial edema, all classical symptoms of HAH toxicity. In an extensive characterization of the effects of PCBs on non-human primates, Tryphonas and colleagues (1991a, b) exposed rhesus monkeys to Aroclor 1254 for 23 to 55 months. The only immune parameter consistently suppressed was the AFC response to sRBC (both IgM and IgG). In addition, after 55 months of exposure, lymphoproliferative responses were dose-dependently suppressed and serum complement levels were significantly elevated. The observed elevation in serum complement has also been reported in PCDD-exposed children from Seveso, Italy (Tognoni and Boniccorsi, 1982) and in PCDD-exposed mice (White *et al.*, 1986).

The effects of PCBs on CMI are far less clear and both suppression and enhancement have been reported. Exposure to Aroclor 1260 has been demonstrated to suppress DTH responses in guinea pigs, whereas exposure to Aroclor 1254 was reported to enhance lymphoproliferative responses in rats. In a similar study in Fischer 344 rats (Aroclor 1254), thymic weight was decreased, NK cell activity was suppressed, PHA-induced proliferative responses were enhanced, and there was no effect on the MLR proliferative response or CTL activity. Other investigators (Silkworth and Loose, 1978, 1979) have reported enhancement of graft-versus-host reactivity and the MLR proliferative response. The augmentation of selected CMI assays may reflect a PCB-induced change in T-cell

subsets (as discussed above with TCDD), which contributes to immune regulation.

Studies on host resistance following exposure to PCBs indicate that the host defenses against herpes simplex virus, *Plasmodium berghei*, *Listeria monocytogenes*, and *Salmonella typhimurium* in mice are suppressed (reviewed by Dean *et al.*, 1985). PCB-induced changes in tumor defenses have not been well defined, and both augmentation and suppression have been reported. This probably reflects the variability in the observed CMI responses.

The immunotoxicological effects of PCBs in humans are unclear. There are four separate reports of a longitudinal study in a cohort of Dutch children suggesting that the developing human immune system may be susceptible to immunotoxic alterations from exposure to Western European environmental levels of dioxin-like compounds, primarily PCBs (ten Tusscher *et al.*, 2003; Weisglas-Kuperus *et al.*, 1995, 2000, 2004). Three industrial areas were compared to a rural area with about 20% less PCBs in maternal plasma. In above studies of Dutch children, the major PCB congeners were measured in plasma in the mother and the newborn, and all dioxin-like compounds in maternal breast milk at two weeks after birth. The results showed an association between dioxin-like compound exposure and immunological changes, which included an increased number of lymphocytes, $\gamma\delta$ T cells, CD3⁺HLA-DR⁺ (activated) T cells, CD8⁺ cells, CD4⁺CD45RO⁺ (memory T cells), and lower antibody levels to mumps and measles vaccination at preschool age (Weisglas-Kuperus *et al.*, 1995, 2000, 2004). In addition, an association was found between dioxin/PCB prenatal exposure and decreased shortness of breath with wheeze, and the PCB burden was associated with a higher prevalence of recurrent middle-ear infections and chicken pox and a lower prevalence of allergic reactions (Weisglas-Kuperus *et al.*, 2000). It is notable that although an association between dioxin/PCB exposure and changes in immune status was observed, all infants were found to be in the normal range. In a second study, modest but persistent changes in immune status were reported in children with perinatal exposure to dioxin-like compounds, as evidenced by a decrease in allergy and increased CD4⁺ T cells and increased CD45RA⁺ cell counts in a longitudinal subcohort of 27 healthy eight-year-old children with documented perinatal dioxin exposure (ten Tusscher *et al.*, 2003). The original cohort at 42 months demonstrated an association among reduced vaccine titers, increased incidence of chicken pox, and increased incidence of otitis media with higher exposure to toxicity equivalents of dioxin. However, by eight years of age the more frequent recurrent ear infections were still apparent (overall), although the chicken pox frequency showed an inverse correlation with PCB/dioxin levels.

Polybrominated Biphenyls The polybrominated biphenyls (PBBs) have been used primarily as flame retardants (Firemaster BP-6 and FF-1). While it is assumed that their profile of activity is similar to that of the PCBs, few studies have actually evaluated the action of the PBBs on immunocompetence. In Michigan (in 1973), Firemaster BP-6 was inadvertently substituted for a nutrient additive in cattle feed, resulting in widespread exposure of animals and humans to PBBs. Studies conducted on livestock following the incident indicated little if any PBB-induced alterations in immunocompetence (Kately and Bazzell, 1978; Vos and Luster, 1989). Like CMI observations involving PCBs, CMI responses in PBB-exposed individuals are not conclusive, showing both a reduction in circulating numbers of T and B cells and a suppression of selected CMI parameters or no effect on CMI at all. In a recent birth cohort study of 384 mother–infant pairs in Eastern Slovakia, PBB concentrations for selected PBB congeners were quantified in maternal and cord serum and infant blood at six months of age. Although

the PBB concentrations in the Eastern Slovakia birth cohort were several-fold higher than those found in the United States, no association was observed between PBB levels, sum total or congener specific, and total serum IgG, IgA, IgM, and IgE (Jusko *et al.*, 2011).

Polycyclic Aromatic Hydrocarbons The polycyclic aromatic hydrocarbons (PAHs) are a ubiquitous class of environmental contaminants. They enter the environment through many routes including the burning of fossil fuels and forest fires. In addition to being carcinogenic and mutagenic, the PAHs have been found to be potent immunosuppressants. Effects have been documented on immune system development, humoral immunity, CMI, and host resistance. The most extensively studied PAHs are 7,12-dimethylbenz[*a*]anthracene (DMBA) and benzo[*a*]pyrene (BaP).

Early immunotoxicology studies of PAHs such as BaP, DMBA, and 3-methylcholanthrene demonstrated suppression of the antibody response to a variety of T-cell-dependent and T-cell-independent antigens. In addition, mice treated with BaP exhibited suppressed lymphoproliferative responses to mitogens, but not alloantigens (Dean *et al.*, 1983). In Dean's studies, host resistance to the PYB6 tumor and to *L. monocytogenes* were unaffected by BaP exposure, as was the DTH response and allograft rejection, suggesting that T cells and CMI were only minimally affected by BaP. In contrast to BaP, DMBA (the more potent PAH) significantly suppressed, not only AFC responses, but also NK cell activity, CTL responses, DTH responses, and alloantigen-induced lymphoproliferative responses. Therefore, DMBA exposure appears to result in long-lasting immune suppression of humoral immunity, CMI, and tumor resistance mechanisms in mice. In addition, both BaP and DMBA also produced significant effects on the bone marrow as evidenced by suppression of pre-B cell formation. A recent comprehensive immunotoxicological evaluation of 1,2:5,6-dibenzanthracene (DBA) demonstrated that a single dose via pharyngeal aspiration at doses up to 30 mg/kg had no effect on NK cell activity, anti-CD3 antibody-mediated T lymphocyte proliferation, the MLR, or B lymphocyte proliferation. In contrast, suppression of the anti-sRBC IgM AFC response was observed at 1.0 mg/kg DBA and the DTH response to *C. albicans* was significantly decreased at 3.0 mg/kg DBA (Smith *et al.*, 2010). In another study, the immunosuppressive activity of various PAHs was greatly enhanced, *in vitro*, when combined with arsenic, a second common environmental contaminant (Li *et al.*, 2010). Interestingly, in this same study it was observed that PAH metabolites were more potent in inducing p53 than their parent compounds.

Significant progress has been made toward elucidation of the mechanism(s) by which PAHs exert their toxicological effects including those on the immune system. Biological and toxicological activity of PAHs is generally dependent on two factors, AHR activation and the metabolism of PAHs to active metabolites by cytochrome P450 isozymes, CYP1A1, CYP1A2 and CYP1B1, which are transcriptionally induced by AHR binding to DREs in the promoter region of the genes that code for the aforementioned isozymes. Although leukocytes, in general, possess modest cytochrome P450 drug-metabolizing activity, *in vitro* studies, splenocytes from naive untreated mice were found to metabolize exogenously added DMBA via P450 enzymes (Ladics *et al.*, 1991). In addition, Ladics and colleagues (1992a, b) demonstrated that macrophages were the primary cell type in a splenic leukocyte preparation capable of metabolizing BaP to 7,8-dihydroxy-9,10-epoxy-7,8,9,10-benzo[*a*]pyrene (BPDE), the reactive metabolite proposed to be the ultimate carcinogenic and immunotoxic form of BaP. These data are consistent with other studies demonstrating the presence and inducibility of CYP1A1, CYP1A2, and most importantly in leukocytes, CYP1B1 (Gao *et al.*, 2005a).

PAHs, including BaP, have also been shown to induce AHR-independent biochemical changes in lymphocytes leading to oxidative stress, activation of tyrosine kinases, and increased intracellular calcium (Mounho and Burchiel, 1998; Pessah *et al.*, 2001). The elevation in intracellular calcium in B and T lymphocytes was shown to be mediated by BaP-7,8-dione and blocked by high concentrations of ryanodine suggesting the involvement of ryanodine receptors (Gao *et al.*, 2005b).

Progress has also been made on the elucidation of the mechanism by which BaP and DMBA mediate bone marrow toxicity, specifically suppression of pre-B-cell formation. In vitro models demonstrated that BaP and DMBA rapidly induced apoptosis in primary pre-B cells and in the pro/pre-B cell line, BU-11 (Yamaguchi *et al.*, 1997). The mechanism for pre-B-cell apoptosis by PAHs was shown to be dependent on bone marrow-derived stromal cells (Yamaguchi *et al.*, 1997), CYP1B1 metabolism (Heidel *et al.*, 1998), and the AHR (Yamaguchi *et al.*, 1997) as well as coinciding with the induction of p53 (Yamaguchi *et al.*, 1997). It has been demonstrated that DMBA-mediated bone marrow cytotoxicity was absent in p53 null mice and that apoptosis of primary bone marrow progenitor B cells cocultured with bone marrow stromal cells and DMBA was p53-dependent (Page *et al.*, 2003). Collectively, these and other studies suggest that PAHs are metabolized by bone marrow stromal cells, which in turn release active PAH metabolites as part of a metabolite protein complex that induces apoptosis in pre-B cells (Allan *et al.*, 2003).

Pesticides

Pesticides include all xenobiotics whose specific purpose is to kill another form of life, including insects (insecticides), small rodents (rodenticides), or even vegetation (herbicides). As such, these chemicals have clear biological activity and many pesticides have been studied for their effects on the immune system (Galloway and Handy, 2003). While there is much evidence that pesticides produce alterations in immune function in a variety of mammalian, amphibian, and fish animal models, the studies described here will focus on those that provide mechanistic information related to epidemiological effects in humans (reviewed by Colosio *et al.*, 2005). Exposure to pesticides occurs most often in occupational settings, in which manufacturers, those applying the pesticides, or those harvesting treated agricultural products, are exposed. In the United States, the most widely used class of pesticides (through 2007) were the organophosphates (Grube *et al.*, 2011), although effects of organochlorines, organotin, carbamates, and the herbicide atrazine will also be discussed.

Organophosphates Organophosphates include malathion, parathion, methyl parathion, diazinon, and chlorpyrifos. Although the neurotoxic effects of organophosphates are well understood to occur via the inhibition of acetylcholinesterase (see Chap. 22, "Toxic Effects of Pesticides"), the mechanism by which these compounds suppress the immune system is not as well defined.

Malathion exhibits both immune suppressive and immune enhancing effects (Rodgers and Ellefson, 1990). Malathion has been shown to suppress humoral immunity as measured by the AFC response to sRBC following a subacute exposure in mice (Casale *et al.*, 1983). In vitro exposure of either human PBMC or murine splenocytes to malathion results in decreased lymphoproliferative responses, suppressed CTL generation, and a decrease in the stimulus-induced respiratory burst in peritoneal cells (Rodgers and Ellefson, 1990). The mechanisms by which malathion is immunotoxic has been attributed to induction of oxidative stress in unstimulated mouse thymocytes (Olgun *et al.*, 2004) or human PBMC

(Ahmed *et al.*, 2011). Parathion has attracted more attention than malathion, probably because it is more acutely toxic. This pesticide also produces mixed responses, which might depend on strain or dose (Casale *et al.*, 1983; Crittenden *et al.*, 1998). A comprehensive screen of various classes of pesticides that exhibit binding affinity to, and activation of, the pregnane X receptor (PXR) demonstrated that parathion activates PXR (Kojima *et al.*, 2011), which has been shown to suppress inflammatory responses through inhibition of NF- κ B (Zhou *et al.*, 2006).

Fewer studies exist that describe the immunotoxicity of diazinon. Recently, it has been shown that diazinon produced gross changes in the spleen and thymus in response to acute doses in mice (Handy *et al.*, 2002; Neishabouri *et al.*, 2004). Diazinon also suppressed humoral immunity as measured by the AFC response to sRBC and CMI as measured by the DTH response following subchronic exposure to mice (Neishabouri *et al.*, 2004).

Chlorpyrifos is one of the most widely used pesticides in the United States (Grube *et al.*, 2011). Similar to other pesticides, its effects on immune function vary. An examination of humans exposed to chlorpyrifos demonstrated suppressed proliferative responses to Con A or PHA, but an increase in auto-antibodies (Thrasher *et al.*, 2002). Using human PBMC, it was demonstrated that chlorpyrifos modestly enhanced or suppressed IFN- γ production in response to LPS at low (1–100 μ g/mL) or high (1000 μ g/mL) concentrations, respectively (Duramad *et al.*, 2006). The mechanism by which chlorpyrifos modulates immunity likely involves ER α , PXR, and AHR, as it induced reporter activity in receptor-activation assays (Kojima *et al.*, 2004, 2011; Takeuchi *et al.*, 2008).

Organochlorines The organochlorines include chemicals such as chlordane, dichlorodiphenyltrichloroethane (DDT), mirex, pentachlorophenol, aldrin, dieldrin, and hexachlorobenzene. Although technically this class of compounds also includes the herbicides 2,4-D and 2,4,5-T, these compounds are considered separately under "Halogenated Aromatic Hydrocarbons." The organochlorines are among the longer-lived pesticides and they have an increased propensity for contamination of soil and ground water, thus providing an additional route of exposure to the general population. Many organochlorine compounds also have been shown to mediate their effects via ER α (DDT, dieldrin, and chlordane), ER β (DDT) (Kojima *et al.*, 2004), or PXR (DDT, dieldrin, and chlordane) (Kojima *et al.*, 2011).

Although DDT has been banned in several countries, it is still used to control malaria, typhoid, and dengue infections in some places of the world. DDT suppresses both humoral immunity and CMI. Early studies demonstrated suppression of humoral immunity following oral gavage in mice (Wiltout *et al.*, 1978). More recently, DDT has been shown to suppress IL-2 production from a human T-cell line and that the mechanism involved suppression of the critical transcription factor NF- κ B (Ndebele *et al.*, 2004). In another study in which occupationally exposed individuals were evaluated for cytokine levels, DDE, a primary metabolite of DDT, was associated with suppression of IL-2 and IFN- γ , and enhancement of IL-4, suggesting an imbalance of Th1/Th2 populations (Daniel *et al.*, 2002). Finally, a correlation between DDE levels in breast milk and incidence of infant ear infections was observed, suggesting increased susceptibility to infection following DDT exposure (Dewailly *et al.*, 2000). An increased susceptibility to infection might also involve suppression of macrophage function by DDT (Nunez *et al.*, 2002), increased apoptosis of macrophages, reduced complement function (Dutta *et al.*, 2008), or suppression of NK cell function (Udoji *et al.*, 2010).

Dieldrin was used from the 1950s until 1987 when its use was banned due to environmental and human health concerns. The humoral immune response to both T-cell-dependent and T-cell-independent antigens is suppressed following exposure to dieldrin (Bernier *et al.*, 1987), and macrophage function from dieldrin-exposed animals are depressed. The apparent effect of dieldrin on macrophages correlates with the increased susceptibility of dieldrin-exposed animals to murine hepatitis virus, which targets macrophages (Krzystyniak *et al.*, 1985). CMI was also suppressed in mice following dieldrin exposure as measured by a suppression of the MLR and graft-versus-host disease (Hugo *et al.*, 1988a, b). Dieldrin is also immunostimulatory under certain conditions as dieldrin enhanced the proinflammatory cytokine IL-8 in vitro and induced neutrophilic inflammation in vivo (Pelletier *et al.*, 2001).

Chlordane refers to a group of structurally related chemicals used to control termites. The principle constituents of chlordane are heptachlor, α -chlordane, γ -chlordane, α -nonachlor, β -nonachlor, α -chlordanene, β -chlordanene, and γ -chlordanene. Definitive immune suppression produced by chlordane was first reported by Spyker-Cranmer and colleagues (1982). In utero exposure resulted in decreased DTH responses in mice with no deficit in antibody production to sRBC. This effect correlated with an increase in resistance to influenza infection because DTH contributes to the pathology of the infection (Menna *et al.*, 1985). In contrast to observations from mice exposed in utero, exposure of adult mice to chlordane did not result in any changes to several immune parameters, including AFC response to sRBC, MLR, DTH response, or mitogenic lymphoproliferation. In rats, immunomodulatory effects of three constituents of chlordane were noted following 28-day oral dosing (technical chlordane, *cis*-nonachlor, and *trans*-nonachlor), the most profound being increased lymphocyte numbers with decreased NK cell activity and proliferation in response to *S. typhimurium* (Tryphonas *et al.*, 2003). The increase in cell numbers was consistent with a study conducted in Japan in which high concentrations of chlordane in breast milk increased CD3⁺ and CD8⁺ T-cell percentages in infants measured at approximately 10 months of age (Nagayama *et al.*, 2007).

Many organochlorine pesticides have also been associated with increased cancer incidence (reviewed by Dich *et al.*, 1997). The mechanism by which this occurs is unclear but is likely multifaceted, including, in part, organochlorine-induced modulation of the immune system. For instance, chlordane suppressed expression of the tumor suppressor, retinoblastoma protein, in a human B-cell/T-cell hybrid cell line (Rought *et al.*, 1999). Furthermore, several organochlorine pesticides were demonstrated in vitro to suppress NK cell activity, which plays a role in defense against tumor formation (Reed *et al.*, 2004). An analysis of the influence of organochlorine exposure and immune gene variants demonstrated increased risk of non-Hodgkin's lymphoma in chlordane-exposed individuals with certain SNPs in IL-10 (Wang *et al.*, 2007), IFN- γ , and IL-4 (Colt *et al.*, 2009).

Organotin Trisubstituted organotins such as tributyltin oxide are widely used as biocides and have recently been recognized as producing some immunotoxic effects. The most prominent action of tributyltin oxide is the induction of profound but reversible thymic atrophy. Studies by Vos and colleagues (1984) demonstrated a decrease in cellularity in the spleen, bone marrow, and thymus. The decrease in splenic cellularity was associated with a concomitant loss of T lymphocytes. In Jurkat T cells, tributyltin oxide increased intracellular calcium and nuclear factor of activated T cells (NFAT) translocation to the nucleus, but the increase in proliferation was not sustained, and at later times, there was decreased proliferation

and increased expression of several apoptotic genes (Katika *et al.*, 2011). In mouse thymocytes, there were increased annexin-V⁺ and Fas ligand-expressing cells following oral administration of tributyltin chloride (Chen *et al.*, 2011), providing additional evidence that thymic atrophy is due to apoptosis.

Another sensitive target of organotin compounds is the NK cell. van Loveren and colleagues (1990) observed suppressed lung NK cytotoxicity in rats exposed orally to tributyltin oxide. The mechanism by which NK cell activity was suppressed has been investigated using human NK cells. Studies have demonstrated an increase in intracellular calcium and increased expression of various AP-1 transcription factors (Lane *et al.*, 2009; Person and Whalen, 2010). However, overall, there was decreased AP-1 binding activity, which the authors suggested was due to increased prevalence of jun-jun homodimers, which exhibit lower affinity for the AP-1 site than other complexes, such as jun-fos heterodimers (Person and Whalen, 2010). Moreover, the mechanism by which di- and tributyltin suppressed NK cell activity might be due to its ability to interact with sulfhydryl groups since glutathione treatment reversed the suppression (Powell *et al.*, 2009).

Carbamates Carbamates, which include carbaryl (Sevin), aldicarb, mancozeb, and sodium methyldithiocarbamate, are used primarily as insecticides. Similar to the organophosphates, the mechanism of action for the neurotoxic effects involves inhibition of acetylcholinesterase. In an evaluation of humoral immunity following a two-week exposure to carbaryl in rats, suppression of the IgM AFC response to sRBC was observed following inhalation exposure, but not oral or dermal exposure (Ladics *et al.*, 1994). Following oral exposure in rats, carbaryl suppressed splenic proliferative responses, but enhanced pulmonary inflammation and IgE, in response to house dust mite, suggesting that carbaryl exhibits tissue-specific effects (Dong *et al.*, 1998). The mechanism by which carbaryl is suppressive involves inhibition of LPS-induced signaling in macrophages (Ohnishi *et al.*, 2008).

Pruett and coworkers (1992a) evaluated the immunotoxicity of sodium methyldithiocarbamate, and observed decreased thymus weight, depletion of the CD4⁺/CD8⁺ population of thymocytes, and profound suppression of NK cell activity following both oral and dermal exposure. They also determined that the mechanism by which sodium methyldithiocarbamate altered cytokine production from peritoneal macrophages involves inhibition of MAP kinase activity via TLR4 (Pruett *et al.*, 2005). Pruet and coworkers (2006) further determined that the mechanism of cytokine alteration involved depletion of glutathione, alteration of copper-dependent proteins, and induction of stress.

Atrazine Atrazine is a herbicide applied to various agricultural crops to control broad leaf weeds. It is widely used in the United States, and it has been detected in soils and ground water because of its resistance to degradation. Similar to other agents discussed, atrazine exhibits immunomodulatory effects. Using offspring of dams treated with atrazine and challenged with antigen, atrazine induced elevations in T-cell proliferation, cytolytic activity, and antigen-specific B cells in male offspring (Rowe *et al.*, 2006). In contrast, young mice directly administered atrazine orally for 14 days exhibited suppressed thymic weight, spleen and thymic cellularity, and B cell fractions, although CD4⁺ T cell numbers increased (Filipov *et al.*, 2005). Similarly, in adult mice, it was confirmed that atrazine suppressed thymic weight, and also suppressed splenic weight and decreased the host resistance of the mice to B16F10 melanoma tumors (Karrow *et al.*, 2005). In vitro, atrazine suppressed cell surface expression of MHCII, CD86, CD11b, and CD11c using a mouse DC line (Pinchuk *et al.*, 2007). Although the

exact mechanism by which atrazine-induced immune suppression occurred is unclear, atrazine treatment of mice does induce corticosterone levels, indicating that activation of the hypothalamic–pituitary–adrenal axis might be involved (Pruett *et al.*, 2003).

Metals

Generally speaking, metals target multiple organ systems and exert their toxic effects via an interaction of the free metal with targets, such as enzyme systems, membranes, or cellular organelles. In considering the immunotoxicity of most metals, it is important to remember that at high concentrations, metals usually exert immunosuppressive effects; however, at lower concentrations, immune enhancement is often observed (Koller, 1980; Vos, 1977). Furthermore, as with most immunotoxic agents, it is important to note that exposures to metals are likely not single exposures, although one metal might dominate depending on the exposure conditions (eg, high levels of mercury in fish or high levels of lead from paint).

Similar to pesticides, there is certainly a large body of literature describing the metal-induced immune alterations in mammalian, amphibian, and fish animal models, but again, the studies described here will focus on those that provide mechanistic information related to epidemiological effects in humans. Moreover, there has been a substantial increase in efforts to understand immune alterations following exposures to metal-containing nanomaterials; for these, the reader is referred to Chap. 28, “Nanotoxicology” or Chap. 23, “Toxic Effects of Metals.” Specific immunotoxic consequences of metal exposure have been reviewed (Zelikoff and Thomas, 1998), but this section focuses on the four best-studied immunotoxic metals: lead, arsenic, mercury, and cadmium.

Lead By far the most consistent finding in studies evaluating the effects of metals on immune responses is increased susceptibility to pathogens. For lead, decreased resistance to the bacterial pathogens *S. typhimurium*, *Escherichia coli*, and *L. monocytogenes* has been observed (reviewed by Kasten-Jolly *et al.*, 2010). In mechanistic studies (reviewed by Dietert and Piepenbrink, 2006a), an alteration in the ability of the macrophage to process and present antigen to antigen-primed T cells confirmed the previous observation and suggested that lead alters immune recognition. Both suppression and enhancement of the AFC response by lead has been reported.

The enhanced AFC response could be due to the observation that lead shifts the T-cell balance from Th1 to Th2 (reviewed by Dietert and Piepenbrink, 2006a). Interestingly, it has been hypothesized that lead exposure might contribute to the development of asthma (Dietert and Piepenbrink, 2006a), a predominantly Th2-mediated disease. This theory is consistent with the observation that there is increased IgE production and asthma incidence in lead-exposed children (Lutz *et al.*, 1999) and that lead inhibits IFN- γ production, a Th1 cytokine (Heo *et al.*, 2007). The mechanism by which lead induces a Th2 switch has been suggested to involve lead-induced alterations in bone marrow-derived DC populations that preferentially stimulate Th2 differentiation (Gao *et al.*, 2007). Additional evidence for lead-induced alteration of APC function comes from the observation that lead-treated APCs stimulated CD4⁺ T-cell proliferation, likely via reduction of myeloid suppressor cell function (myeloid suppressor cells are macrophages that control T-cell proliferation) (Farrer *et al.*, 2005, 2008).

Arsenic A challenge in understanding the mechanisms by which arsenic is immunotoxic is that in addition to inconsistencies that arise from route of administration, concentrations/doses, and

species/strain differences, the speciation of arsenic plays a significant role in arsenic toxicity. Moreover, early studies demonstrated the intricate interplay among the host, the pathogen, and the xenobiotic. Following exposure to the semiconductor material gallium arsenide, there was modest protection against infection of either *S. pneumoniae* or *L. monocytogenes*, but resistance to the B16F10 melanoma was reduced. It was subsequently determined that the arsenic concentrations in the blood of these animals was high enough to offer a chemotherapeutic effect against the bacterial pathogens (Burns *et al.*, 1993).

Arsenic compounds affect human immune function. For instance, in environmentally exposed children, there was a correlation between total arsenic in urine (inorganic and arsenic metabolites) and superoxide anion production from stimulated monocytes (Luna *et al.*, 2010) and in adult smelter workers, higher levels of urinary arsenic correlated with increased lipid peroxidation and lower vitamin E levels in blood (Escobar *et al.*, 2010). These results suggest that arsenic exposure causes oxidative stress and in fact, using the THP-1 monocytic cell line, it was shown that arsenic trioxide decreased glutathione levels and induced heme oxygenase, which is often induced to combat oxidative stress (Wang *et al.*, 2011).

There are also several studies in which human PBMC from unexposed individuals were treated in vitro with arsenic compounds. The percentage of IL-2-producing T cells in human PBMC was suppressed following treatment with sodium arsenite (Galicia *et al.*, 2003). An additional study showed that sodium arsenite suppressed IL-2 production while also stimulating heme oxygenase in purified T cells, indicating that the direct T-cell impairment by arsenic occurs in parallel with oxidative stress (Martin-Chouly *et al.*, 2011). B-cell and accessory cell (ie, macrophage) function is also compromised by arsenic compounds, as suggested by early anti-sRBC AFC responses in mice (Sikorski *et al.*, 1991). Interestingly, in spite of a fairly extensive database showing suppression of antibody responses in murine models, in purified human B cells stimulated with CD40L, sodium arsenite did not suppress IgM production (Lu *et al.*, 2009). Finally, treatment of primary human macrophages with arsenic trioxide resulted in decreased expression of CD14 (a PRR and coreceptor of TLRs), and altered the morphology thereby suppressing adhesion (Lemarie *et al.*, 2006). The alterations in macrophage function were dependent on arsenic trioxide-induced activation of RhoA (small GTPase and Ras homolog) (Lemarie *et al.*, 2006). At higher concentrations, arsenic trioxide also induced apoptosis of macrophages through inhibition of NF- κ B signaling (Lemarie *et al.*, 2006). Induction of macrophage apoptosis is the basis for the therapeutic use of arsenic trioxide to treat acute promyelocytic leukemia.

Mercury Mercury compounds include organic (ie, methyl mercury) or inorganic forms. Mercury compounds not only suppress immunological responses, but also induce autoimmunity (see Mercury discussion under the “Autoimmunity” section). Interestingly, in one genetically susceptible mouse model of autoimmunity, subcutaneous administration of methyl mercury reduced T and B cell numbers prior to autoimmunity induction, demonstrating the immunomodulatory actions of mercury in vivo (Haggqvist *et al.*, 2005).

Similar to arsenic, the mechanism by which mercury compounds are immunotoxic might be induction of apoptosis. Mercury also induces oxidative stress as evidenced by glutathione depletion (Mondal *et al.*, 2005). Several studies have examined the effect of in vitro treatment of human PBMC with mercury compounds. Using mercuric chloride in PBMC stimulated with either anti-CD3/CD28/CD40 or bacterial antigen demonstrated that mercury differentially

affects Th1/Th2 cytokines depending on the mode of T-cell activation (Hemdan *et al.*, 2007). Using LPS to stimulate inflammatory cytokines, mercuric chloride enhanced an inflammatory response (Gardner *et al.*, 2009). The induction of proinflammatory cytokines was also observed in Brazilian gold miners using mercury as an amalgam. Mercury-exposed miners demonstrated higher levels of IL-1 β , TNF- α , and IFN- γ (Gardner *et al.*, 2010). The mechanism for cytokine induction could be due to mercury-induced phosphorylation of ERK and p38 MAPKs as demonstrated using mercuric chloride in Jurkat T cells. This was due, in part, to ROS since mercury-induced phosphorylation of ERK and p38 MAPKs was abrogated by *N*-acetylcysteine (Haase *et al.*, 2011).

Cadmium Like other metals, cadmium exhibits immunomodulatory effects. Early studies demonstrated that oral administration of cadmium to mice increased susceptibility to herpes simplex type 2 virus, suppressed T and B cell proliferation, but enhanced macrophage phagocytosis (Thomas *et al.*, 1985). As with many other immunotoxic agents, it has been suggested that the stress response, a shift to a Th2 cell population, induction of oxidative stress and induction of apoptosis all contribute to the mechanism by which cadmium suppresses humoral immunity and CMI (Hemdan *et al.*, 2006; Lall and Dan, 1999; Pathak and Khandelwal, 2006, 2008). Using human HSCs isolated from umbilical cord blood, it was shown that *in vitro* treatment with cadmium chloride activated autophagy, an internal cellular degradation pathway allowing clearance of damaged cellular components (Di Gioacchino *et al.*, 2008). Cadmium-induced oxidative stress was confirmed in PBMC isolated from a Japanese population of women living in a cadmium polluted area in which higher blood and urinary cadmium correlated with increased expression of several genes involved in oxidative stress signaling (Dakeshita *et al.*, 2009).

It has long been known that cadmium (and other metals, such as mercury) bind to a protein called metallothionein, which is a small, cysteine-rich protein that complexes normally with divalent cations, such as copper and zinc. The role of metallothionein in metal-induced immunotoxicity has been recently reviewed (Klaassen *et al.*, 2009), and there are several mechanisms by which the cadmium–metallothionein complex might contribute to immune modulation. The binding of cadmium to metallothionein could displace copper or zinc, altering the availability of the latter cations for biochemical processes. Alternatively, metallothionein is induced in response to several stimuli, including metals, and it has been demonstrated that metallothionein influences lymphocyte proliferation, differentiation, and various effector functions. Finally, since metallothionein is a cysteine-rich protein, it also plays a role in the oxidative homeostasis of the cell, which could be compromised under conditions of oxidative stress.

Solvents and Related Chemicals

There is limited but substantive evidence that exposure to organic solvents and their related compounds can produce immune suppression. Chemicals included in this section are aromatic hydrocarbons, such as benzene, haloalkanes and haloalkenes, glycols and glycol ethers, and nitrosamines.

Aromatic Hydrocarbons By far the best-characterized immunotoxic effects by an organic solvent are those produced by benzene. In animal models, benzene induces anemia, lymphocytopenia, and hypoplastic bone marrow. In addition, it has been suggested that this myelotoxicity may be a result of altered differentiative capacity in bone marrow-derived lymphoid cells. Benzene (oral and inhaled) exposure has been reported to alter both humoral and

CMI parameters including suppression of the anti-sRBC antibody response, decreased T- and B-cell lymphoproliferative responses (mitogens and alloantigens), and suppression of CTL activity. Benzene exposure also appears to increase the production of both IL-1 and TNF- α and to suppress the production of IL-2. With these dramatic effects on immune responses, it is not surprising that animals exposed to benzene exhibit reduced resistance to a variety of pathogens. In terms of a possible mechanism of action, Pyatt *et al.* (1998) demonstrated that hydroquinone, a reactive metabolite of benzene, inhibited the activity of NF- κ B, a transcription factor known to regulate the expression of a number of genes critical for normal T-cell function. The authors concluded that NF- κ B might be an important molecular mediator of the immunotoxicity of hydroquinone (and benzene).

A number of compounds structurally related to benzene have also been studied for their potential effects on the immune system. For example, nitrobenzene (an oxidizing agent used in the synthesis of aniline and benzene compounds) has been reported to produce immunotoxic effects (Burns *et al.*, 1994b), with the primary targets being erythrocytes and bone marrow. Immunomodulating activity has also been observed for toluene, although most effects occur at markedly high concentrations. When compared with benzene, toluene has little to no effect on immunocompetence. However, it is noteworthy that toluene exposure effectively attenuates the immunotoxic effects of benzene (probably because of competition for metabolic enzymes). In contrast to the parent toluene, the mono-substituted nitrotoluenes (*para*- and *meta*-nitrotoluene) do significantly alter the immune system (Burns *et al.*, 1994a, c). Exposure to *p*-nitrotoluene has been demonstrated to suppress the antibody response to sRBC, to decrease the number of CD4⁺ splenic T cells, and to suppress the DTH response to KLH. In addition, host resistance to *L. monocytogenes* was impaired, suggesting the T cell as a primary target. Similarly, *m*-nitrotoluene suppresses the antibody response to sRBC, the DTH response to KLH, T-cell mitogenesis, and host resistance to *L. monocytogenes*, again suggesting the T cell as the cellular target. The disubstituted nitrotoluene (2,4-dinitrotoluene) is also immunosuppressive (Burns *et al.*, 1994a), with exposure resulting in suppressed humoral immunity, NK cell activity, and phagocytosis by splenic macrophages. Host resistance to bacterial challenge was also impaired. This profile of activity following exposure to 2,4-dinitrotoluene is consistent with a perturbation of the differentiation and maturation of leukocytes.

Haloalkanes and Haloalkenes Carbon tetrachloride is widely recognized as hepatotoxic. Studies in mice revealed that carbon tetrachloride is also immunosuppressive. Mice exposed for 7 to 30 days to carbon tetrachloride (orally or intraperitoneally) exhibited a decreased T-cell-dependent antibody response (sRBC), suppressed MLR response, and lower lymphoproliferative capacity (T and B cells) (Kaminski *et al.*, 1989a). *Ex vivo* activation of splenic T cells isolated from carbon tetrachloride-treated mice revealed a marked enhancement in IL-2 production. Moreover, the effect on IL-2 by carbon tetrachloride was associated with a serum factor in treated animals as direct addition of serum from carbon tetrachloride-treated mice also produced strong enhancement of IL-2 in naive activated splenic T cells. Further characterization demonstrated that exposure to carbon tetrachloride caused the induction and release of TGF- β_1 from the liver. The timing and conditions for the carbon tetrachloride-induced releases of TGF- β_1 was concomitant with the onset of immune suppression. Addition of anti-TGF- β_1 neutralizing antibodies abrogated IL-2 enhancement by serum isolated from carbon tetrachloride-treated mice, suggesting that the enhancing effects on IL-2 were mediated indirectly through

TGF- β_1 released from the liver (Delaney *et al.*, 1994; Jeon *et al.*, 1997). Induction or inhibition of liver cytochrome P450 activity augmented and blocked, respectively, the immunotoxic actions of carbon tetrachloride, suggesting a requirement for metabolism in order for carbon tetrachloride to be immunosuppressive (Kaminski *et al.*, 1990). Subsequently, it was demonstrated that TGF- β_1 produces profound effects on IL-2 regulation. Specifically, results in mouse spleen cells showed that TGF- β_1 exerts bifunctional effects on IL-2 and lymphoproliferation as evidenced by the fact that TGF- β_1 stimulates IL-2 production at low concentrations (0.1–1 pg/mL) and conversely suppresses IL-2 production at high concentrations (1–10 ng/mL), when activated using monoclonal antibodies directed against the CD3 complex and CD28 (McKarns and Kaminski, 2000). Additionally, concentrations of TGF- β_1 that stimulated IL-2 production concomitantly suppressed splenocyte proliferation under similar conditions. Studies have revealed that IL-2 regulation by TGF- β_1 is mediated, at least in part, via a mechanism dependent on SMAD3, a transcription factor involved in signaling through the TGF- β receptor (McKarns *et al.*, 2004). In studies comparing acute versus subchronic carbon tetrachloride administration, acute carbon tetrachloride treatment enhanced phagocytosis and NK cell activity while subchronic treatment significantly impaired phagocytosis and NK cell activity (Jirova *et al.*, 1996). In contrast, Fischer 344 rats exposed orally for 10 days showed no immunotoxic effects, despite signs of liver toxicity (Smialowicz *et al.*, 1991c). The difference in sensitivity between studies in the mouse and rat may represent differences in the metabolic capabilities between these two species as well as the degree of liver injury induced, and hence the magnitude of TGF- β_1 production.

There is relatively little information on solvents and other chemicals structurally related to carbon tetrachloride. Some early studies were conducted to assess the potential immunotoxicity of a number of drinking water contaminants. Exposure to dichloroethylene (in drinking water for 90 days) has been reported to suppress the anti-sRBC antibody response in male CD-1 mice and to inhibit macrophage function in females (Shopp *et al.*, 1985). Similarly, exposure to trichloroethylene (in the drinking water for four–six months) was reported to inhibit both humoral immunity and CMI and bone marrow colony-forming activity (Sanders *et al.*, 1982). In those experiments, females were more sensitive than males. Exposure to 1,1,2-trichloroethane resulted in suppression of humoral immunity in both sexes. In addition, macrophage function was suppressed (males only) (Sanders *et al.*, 1985). Inhalation studies with dichloroethane, dichloromethane, tetrachloroethane, and trichloroethane indicated that the pulmonary host resistance to *Klebsiella pneumoniae* was suppressed (Aranyi *et al.*, 1986; Sherwood *et al.*, 1987), suggesting that alveolar macrophages may be affected. More recent work with this series of solvents indicated that exposure to trichloroethylene may be an effective developmental immunotoxicant in B6C3F1 mice, suggesting that additional studies are required to determine the health risks associated with developmental exposure to this chemical (Peden-Adams *et al.*, 2006).

Glycols and Glycol Ethers Exposure to glycol ethers has been associated with adverse effects in laboratory animals, including thymic atrophy and mild leukopenia. Oral administration of ethylene glycol monomethyl ether for one to two weeks (House *et al.*, 1985; Kayama *et al.*, 1991) or its metabolite methoxyacetic acid for two weeks (House *et al.*, 1985) produced decreased thymic weight, thymic atrophy, and a selective depletion of immature thymocytes in mice. No alterations in humoral immunity, CMI, macrophage function, or host resistance to *L. monocytogenes* were observed (House *et al.*, 1985). It has also been suggested that perinatal

exposure to ethylene glycol monomethyl ether may produce thymic hypocellularity and inhibition of thymocyte maturation, and that it may affect polymphocytes in fetal liver (Holladay *et al.*, 1994).

Oral studies (5–10 days) on the glycol ether 2-methoxyethanol have consistently shown a decrease in thymus weight in the rat (Smialowicz *et al.*, 1991a; Williams *et al.*, 1995). This decrease is often accompanied by alterations in lymphoproliferative responses, although suppression is seen in some cases and stimulation in others, with no clear reason for the differences in response. Alterations in spleen weight and splenic cell populations have also been observed, as well as suppression of trinitrophenyl-LPS and anti-sRBC AFC responses. Similar results have been obtained following dermal exposure to 2-methoxyethanol (Williams *et al.*, 1995). A decrease in IL-2 production has also been reported (Smialowicz *et al.*, 1991a). Studies using the metabolites of 2-methoxyethanol (methoxyacetaldehyde and methoxyacetic acid) or specific metabolic pathway inhibitors have shown that methoxyacetaldehyde and methoxyacetic acid are more immunotoxic than 2-methoxyethanol alone (methoxyacetaldehyde > methoxyacetic acid > 2-methoxyethanol) (Kim and Smialowicz, 1997; Smialowicz *et al.*, 1991a, b), suggesting a role for metabolism in the observed alterations in immunocompetence. Although there was no effect following 10-day oral exposures to 2-methoxyethanol (50–200 mg/kg per day) (Smialowicz *et al.*, 1991a), subchronic exposure for 21 days to 2000 to 6000 ppm (males) or 1600 to 4800 ppm (females) did produce an enhanced NK cell response (Exon *et al.*, 1991) in addition to suppression of the AFC response and a decrease in IFN- γ production.

Nitrosamines The nitrosamine family of chemicals comprises the nitrosamines, nitrosamides, and *C*-nitroso compounds. Exposure to nitrosamines, especially *N*-nitrosodimethylamine (eg, also known as dimethylnitrosamine or DMN; and the most prevalent nitrosamine) comes primarily through industrial and dietary means, and minimally through environmental exposure. DMN is used commonly as an industrial solvent in the production of dimethylhydrazine. It has been used as an antioxidant, as an additive for lubricants and gasolines, and as a softener of copolymers. The toxicity and immunotoxicity of DMN have been extensively reviewed (Myers and Schook, 1996). Single or repeated exposure to DMN inhibits T-dependent humoral immune responses (IgM and IgG), but not T-independent responses. Other symmetrical nitrosamines, such as diethylnitrosamine, dipropylnitrosamine, and dibutylnitrosamine, demonstrated similar effects on humoral immunity but were not as potent as DMN (Kaminski *et al.*, 1989b). In fact, as the length of the aliphatic chain increased, the dose required to suppress the anti-sRBC AFC response by 50% (ED₅₀) also increased. In contrast, nonsymmetrical nitrosamines suppressed humoral immunity at comparable concentrations. Overall, the rank order of ED₅₀ values paralleled their LD₅₀ values. T-cell-mediated lymphoproliferative responses (mitogens or MLR) and DTH response were also suppressed following DMN exposure. In vivo exposure to DMN followed by challenge with several pathogens did not produce a consistent pattern of effects: decreased resistance to *Streptococcus zooepidemicus* and influenza, no effects on resistance to herpes simplex types 1 or 2 or *Trichinella spiralis*, and increased resistance to *L. monocytogenes*. In contrast, anti-tumor activity in DMN-exposed animals was consistently enhanced. DMN-exposed animals also have altered development of hematopoietic cells (increased macrophage precursors). Taken together, these data suggest the macrophage (or its developmental precursors) as a primary target. Mechanistic studies have demonstrated that DMN-induced alterations in CMI are associated with enhanced macrophage activity, increased myelopoietic activity, and

alterations in TNF- α transcriptional activity. It has been postulated that DMN may cause the enhanced production of GM-CSF, which can have autocrine (enhanced tumoricidal and bactericidal activity) and paracrine (induced secretion of T-cell-suppressing cytokines by macrophages) activities.

Mechanistic studies have also indicated a critical role for metabolism in the immune suppression by DMN (Haggerty and Holsapple, 1990; Johnson *et al.*, 1987; Kim *et al.*, 1988). It is known that DMN is metabolized by the liver cytochrome P450 system to a strong alkylating agent, and studies have shown that there is a relationship between DMN-induced immune suppression and the anticipated hepatotoxicity. Interestingly, a molecular dissection of DMN-induced hepatotoxicity by mRNA differential display demonstrated an increase in transcripts for the complement protein C3 and serum amyloid A (Bhattacharjee *et al.*, 1998). Previous work by Kaminski and Holsapple (1987) had demonstrated the potential immune suppression associated with an increase in serum amyloid A.

Mycotoxins

Mycotoxins are structurally diverse secondary metabolites of fungi that grow on feed. This class of chemicals comprises such toxins as aflatoxin, ochratoxin, and the trichothecenes, notably T-2 toxin and deoxynivalenol (vomitoxin). As a class, these toxins can produce cellular depletion in lymphoid organs, alterations in T- and B-lymphocyte function, suppression of antibody responses, suppression of NK cell activity, decreased DTH responses, and an apparent increase in susceptibility to infectious disease (reviewed by Bondy and Pestka, 2000; IPCS, 1996). T-2 toxin has also been implicated as a developmental immunotoxicant, targeting fetal lymphocyte progenitors leading the thymic atrophy often observed with these mycotoxins (Holladay *et al.*, 1993). For ochratoxin, at least, the dose, the route of administration, and the species appear to be critical factors in results obtained in immunotoxicity studies. Past studies with aflatoxin B1 suggest that CMI and phagocytic cell functions are affected as evidenced by decreased proliferative responses to PHA and suppression of DTH responses (Raisuddin *et al.*, 1993). In addition, *in vitro* experiments demonstrated that aflatoxin B1 required metabolic bioactivation in order to produce suppression of antibody responses and of mitogen-induced lymphoproliferation (Yang *et al.*, 1986). Studies in laboratory animals have also shown increased risk to secondary infection after aflatoxin B1 treatment. The effects of aflatoxins on the human immune system have not been characterized but are of concern in light of the fact that in many parts of the world, such as in West Africa, exposure to aflatoxins is widespread as studies in Benin and Togo found that 99% of children possessed measurable aflatoxin-albumin adducts in blood (Gong *et al.*, 2003).

For the extensively studied trichothecenes, the mechanism of immune impairment is related in part to inhibition of protein synthesis. Interestingly, trichothecenes at high doses induce leukocyte apoptosis concomitantly with immune suppression (Pestka *et al.*, 1994). Conversely, at low doses, trichothecenes promote expression of a diverse array of cytokines including IL-1, IL-2, IL-5, and IL-6. In addition, trichothecenes activate mitogen-activated protein kinases *in vivo* and *in vitro* via a mechanism known as the ribotoxic stress response (Chung *et al.*, 2003; Moon and Pestka, 2002; Zhou *et al.*, 2003). Prolonged consumption of deoxynivalenol by mice was shown to induce elevation of IgA and IgA immune complex formation, and kidney mesangial IgA deposition (Pestka, 2003). It has been postulated that the enhancement in IgA production induced by deoxynivalenol may be associated with the increase in

cytokine production described above. The trichothecenes are currently considered among the most potent small-molecule inhibitors of protein synthesis in eukaryotic cells, which is dichotomous to the observed increase in IgA secretion.

Adverse health effects have been associated with damp indoor environments following building envelope breach resulting from heavy rains and/or flooding, as occurred during Hurricanes Katrina and Rita in the Gulf Coast of the United States. The adverse health effects have been attributed, at least in part, to the presence of molds, most notably *Stachybotrys chartarum*, also known as black mold. *S. chartarum* produces the macrocyclic trichothecene toxin, satratoxin G, which like many of the trichothecenes is a potent inhibitor of protein synthesis. In a recent study, satratoxin G exposure of mice, 100 $\mu\text{g}/\text{kg}$ for five consecutive days by intranasal instillation, induced apoptosis of olfactory sensory neurons and neutrophilic rhinitis (Islam *et al.*, 2006). Elevated mRNA levels for proinflammatory cytokines TNF- α , IL-6, and IL-1, and the chemokine, MIP-2, were detected in nasal airways and the adjacent olfactory bulb of the brain. By Day seven, marked atrophy of the olfactory nerve and glomerular layer of the olfactory bulb was detected. These findings suggest that neurotoxicity and inflammation within the nose may be potential adverse health effects associated with *Stachybotrys* exposure in indoor air.

Natural and Synthetic Hormones

It is well established that a sexual dimorphism exists in the immune system. Females have higher levels of circulating Igs, a greater antibody response, and a higher incidence of autoimmune disease than males. Males appear to be more susceptible to the development of sepsis and the mortality associated with soft tissue trauma and hemorrhagic shock. Specific natural sex hormones in this dichotomy have been implicated. Immune effects of androgens and estrogens appear to be very tightly controlled within the physiological range of concentrations, and profound changes in immune activity can result from very slight changes in concentrations of hormones.

Estrogens Diethylstilbestrol is a synthetic nonsteroidal compound possessing estrogenic activity. Diethylstilbestrol was used in men to treat prostate cancer and in women to prevent threatened abortions, as an estrogen replacement, and as a contraceptive drug. Extensive functional and host resistance studies on diethylstilbestrol (mg/kg per day range) have indicated that exposure to this chemical results in alterations in CMI and/or macrophage function and are believed to be mediated by the presence of the estrogen receptor on immune cells (Brown *et al.*, 2006a,b; Holsapple *et al.*, 1983; Kalland, 1980; Lai *et al.*, 2000; Luster *et al.*, 1980, 1984). Targeted sites of action include the thymus (thymic depletion, alteration in T-cell maturation process), T cells (decreased MLR, DTH, and lymphoproliferative responses), and macrophage (enhanced phagocytic, antitumor, and suppressor function). Pre- and neonatal exposures (mg/kg per day dose range) have also demonstrated immunotoxic effects related to T-cell dysfunction. DTH and inflammatory responses associated with diethylstilbestrol exposure in adult mice have been shown to be reversible upon cessation of exposure (Holsapple *et al.*, 1983; Luster *et al.*, 1980). However, effects from *in utero* and neonatal exposures appear to have more lasting, possibly permanent effects on immune responses (Kalland *et al.*, 1979; Luster *et al.*, 1979; Ways *et al.*, 1980).

Exposure of human PBMC from men and women to 17 β -estradiol (E2) increased basal IgM, IgG, and IL-10 production with no effect on IL-1 α , IL-1 β , IL-2, IL-4, and IL-6. Interestingly, addition of IL-10 enhanced the effect of E2 on IgM and IgG production (Kanda *et al.*, 1999). IL-10 appears to have both positive

and negative effects on immune function since in mouse models IL-10 is the mediator of a Breg subset (ie, B10 or Br1). Similar to the above results, E2 enhanced the induction of IgM and IgA AFCs from PBMC stimulated with pokeweed mitogen (testosterone had no effect) (Paavonen *et al.*, 1981). In an autoimmune disease state, basal IgG production was more markedly induced by E2 in patients with active systemic lupus erythematosus (SLE) as compared to normal donors. In addition to an increase in total IgG, E2 also induced anti-dsDNA antibody (absent in normal donors). The profile was somewhat different for inactive SLE patients in that E2 increased total IgG production to a similar degree as SLE patients, but E2 did not induce anti-dsDNA antibody, which had a lower basal level than active SLE (Kanda *et al.*, 1999). Furthermore, microarray analysis of T cells purified from human PBMC demonstrated E2-altered gene expression for cellular signaling proteins in activated T cells from SLE patients versus controls (Walters *et al.*, 2009). Isoflavones (“isoflavone intervention”) administered for 16 weeks to postmenopausal women through soy milk or supplemental tablets resulted in higher frequency of B cells in peripheral blood with no effect on the frequency of CD4⁺, CD8⁺, or NK subsets. The isoflavone intervention had no effect on IL-2 or TNF- α plasma levels, but IFN- γ trended toward an almost twofold nonsignificant increase (Ryan-Borchers *et al.*, 2006). Other studies demonstrated an increase in plasma IL-6 with isoflavone diets (73 mg per day) (Jenkins *et al.*, 2002) and increased cytotoxicity of human PBMC NK cells with isoflavone metabolites (0.1 μ mol/L) (Zhang *et al.*, 1999). In contrast to the human results with E2, *in vivo* administration of the phytoestrogen, genistein, suppressed anti-KLH IgG titers in mice (Yellayi *et al.*, 2002). However, mouse cells treated with E2, diethylstilbestrol, or bisphenol A (discussed below) enhanced IgG anti-DNA antibody production and IgG immune complex deposition in the kidney, which may be a result of increased autoantibody secretion from B-1 cells (Yurino *et al.*, 2004). Additionally, E2 has been shown to drive the expansion of the mouse Treg cell compartment and to increase Treg activity (Luo *et al.*, 2011; Polanczyk *et al.*, 2004). E2 was also shown in mice to inhibit recruitment and activation of inflammatory cells resulting in inhibition of TNF- α and IFN- γ production and of the inflammatory response (Salem *et al.*, 2000). These discrepancies in the effects of E2 (activation vs. inhibition) may be due to species differences, different cellular targets, or a lack of disease state. Taken together, it is clear that E2 and phytoestrogens alter the human antibody response, an effect that is more marked in an autoimmune disease state.

A potential mechanism for the effects by estrogen and estrogenic compounds is activation of the nuclear estrogen receptor (ER, α , or β isoform), which is ubiquitously expressed in most tissues. Binding of ligand stabilizes ER dimers, which then bind to estrogen response elements (ERE) in target genes leading to transcriptional activation or inhibition. A recent and in-depth review outlines the studies demonstrating ER expression and ER-mediated effects in T cells, B cells, and APCs as well as a role of ER in murine models of autoimmunity (Cunningham and Gilkeson, 2011). In resting and activated human PBMC, CD4⁺ T cells expressed higher levels of ER α than B cells which expressed higher levels of ER β . CD8⁺ cells express ER α and ER β equally, but at low levels (Phiel *et al.*, 2005). ER α and ER β are differentially expressed in APCs (Cunningham and Gilkeson, 2011) and in human secondary lymphoid tissues (Shim *et al.*, 2006). Additionally, estrogen and the ER appear to play a significant role in autoimmunity. Ovariectomy before sexual maturation resulted in a significant suppression in a murine model of SLE, which could be reversed by supplementary estrogen treatment (Talal, 1981). ER knockout studies have primarily corroborated this finding with knockout of ER α in three

different mouse models of SLE showing attenuation of the disease and prolonged survival (Bynote *et al.*, 2008; Svenson *et al.*, 2008). This effect was selective for ER α since ER β did not alter the disease state (Svenson *et al.*, 2008). In contrast to these results, ER α (but not ER β) knockout in a mildly autoimmune prone mouse strain led to signs of autoimmunity and spontaneous (no antigen challenge) formation of germinal centers in the spleen (Shim *et al.*, 2004). An additional consideration in elucidating the mechanisms by which the ER mediates biological effects is the extensive cross talk that can occur between the ER and other receptor signaling pathways (eg, AHR and PPAR) and transcription factors (eg, AP-1 and NF- κ B) that may be independent of the ERE.

Bisphenol A, a monomer in polycarbonate plastics and a constituent of epoxy and polystyrene resins possessing weak binding affinity for the estrogen receptor, has been recently evaluated by a number of laboratories for its potential to affect various aspects of immune function. The majority of studies to date demonstrate that leukocytes cultured in the presence of very high concentrations (>1 μ M) of bisphenol A exhibit a number of alterations primarily in innate immune function responses including suppression of LPS-induced nitric oxide production and TNF- α secretion by macrophages (Kim and Jeong, 2003). The effects on nitric oxide production were shown to be correlated with a decrease in NF- κ B DNA binding activity, a transcription factor critically involved in the regulation of inducible nitric oxide synthase and TNF- α . In this study, suppression by bisphenol A of LPS-induced nitric oxide production was blocked by the estrogen receptor antagonist, ICI 182,780. Bisphenol A (10–50 μ M) has also been reported to enhance IL-4 production in a model of a secondary immune response (Lee *et al.*, 2003). *In vivo* treatment of mice with bisphenol A (2.5 mg/kg) for seven days produced a decrease in *ex vivo* Con A-induced proliferation and IFN- γ secretion, but had no effect on the number of CD4⁺, CD8⁺, and CD19⁺ cells in the spleen (Sawai *et al.*, 2003). Additional studies corroborate these findings by demonstrating an augmentation of Th1 immune responses (ie, cytokine profile and increased expression of antigen-specific IgG_{2a} and IgA) with one study showing increased Th1 and Th2 immune responses. In these studies, bisphenol A was administered either by *i.p.* injection (0.1 mg/g) four times every second day (Alizadeh *et al.*, 2006) in drinking water (10 mg/L, *ad libitum*) for two weeks (Goto *et al.*, 2007) or through maternal dosing (3–3000 μ g/kg) for 18 days (Yoshino *et al.*, 2004). Presently, the putative effects of bisphenol A on immune function are poorly defined and based on the current literature, it is unclear whether the majority of the immunomodulatory effects reported are mediated through an ER-dependent mechanism. Additionally, the relatively high potential for human exposure to bisphenol A due to its wide use in plastics and other products has been of considerable concern to the public and government regulators. Despite the large number of safety-related studies published on bisphenol A, there is considerable controversy regarding its safety and the current tolerable daily intake value (0.05 mg/kg body weight per day) (Hengstler *et al.*, 2011; Sekizawa, 2008; Vandenberg *et al.*, 2009).

Androgens Oxymetholone is a synthetic androgen structurally related to testosterone and was used in the past in the treatment of pituitary dwarfism and as an adjunctive therapy in osteoporosis. Its current use is limited to treatment of certain anemias. Oxymetholone was administered orally to male mice daily for 14 consecutive days (50–300 mg/kg per day) resulting in a minimal decrease in CMI (MLR and CTL response) but without altering the ability of the animals to resist infection in host resistance assays (Karrow *et al.*, 2000). In contrast, anabolic androgenic steroids have been shown to significantly suppress the sRBC AFC response

and to increase the production of proinflammatory cytokines from human PBMC.

No comprehensive studies evaluating the effects of testosterone on immune parameters have been conducted. However, it is clear that testosterone is capable of contributing to the suppression of immune function; in particular, CMI responses and macrophage activity. There are numerous reports in the clinical literature that males are more susceptible than females to infection following soft tissue trauma and hemorrhagic shock (reviewed by Catania and Chaudry, 1999). Treatment of males with agents that block testosterone (eg, flutamide) can prevent the trauma- and hemorrhage-induced depression of immunity. Similarly, treatment of females with dihydrotestosterone prior to trauma-hemorrhage results in depression of CMI similar to that of males. Furthermore, gonadectomized mice of either sex have elevated immune responses to endotoxin, which can be attenuated in either sex by the administration of testosterone. The mechanisms in these cases, including influences by the neuroendocrine system, are not clear. Other investigators have reported that, like estrogenic agents, testosterone and other androgens are capable of influencing host defense by altering lymphocyte trafficking in the body and altering the ability of the macrophage to participate in immune responses. It is uncertain if these responses are mediated by the cytosolic androgen receptor, which like the ER, is part of the nuclear receptor superfamily and regulates gene transcription by binding androgen response elements in target genes.

Glucocorticoids The immunosuppressive actions of corticosteroids have been known for years. Following binding to a cytosolic receptor, these agents produce profound lymphoid cell depletion in rodent models. In non-human primates and humans, lymphopenia associated with decreased monocytes and eosinophils and increased neutrophils are seen. Corticosteroids induce apoptosis in rodents, and T cells are particularly sensitive. In addition, these agents suppress macrophage accessory cell function, the production of IL-1 from the macrophages, and the subsequent synthesis of IL-2 by T cells. In general, corticosteroids suppress the generation of CTL responses, MLR, NK cell activity, and lymphoproliferation. While it is clear that these drugs suppress T-cell function, their effects on B cells are not completely clear. Corticosteroids suppress humoral responses, but this appears to be due to effects on T cells, as antigen-specific antibody production by B cells to T-independent antigens does not appear to be affected by corticosteroid treatment.

In spite of the wide therapeutic use of glucocorticoids, the mechanism of action by which glucocorticoids mediate their anti-inflammatory/immunosuppressive activity is not well understood. Several mechanisms have been proposed all of which involve activation of the glucocorticoid receptor. Binding of glucocorticoids to the cytosolic glucocorticoid receptor (member of the nuclear receptor superfamily) induces the receptor to function as a ligand-activated transcription factor that undergoes homodimerization and DNA binding to glucocorticoid response elements (GREs) in the regulatory regions of glucocorticoid-responsive genes. Depending on the gene, GRE can either positively or negatively regulate transcription. For example, glucocorticoids induce annexin 1 (lipocortin 1), a calcium and phospholipid binding protein, which acts to inhibit PLA2 (Goulding and Guyre, 1992; Taylor *et al.*, 1997). Inhibition of PLA2 results in a decrease in arachidonate formation, the precursor in the biosynthesis of inflammatory prostaglandins and leukotrienes. Similarly, glucocorticoids induce transcription of I κ B, which is the endogenous inhibitor of the transcription factor, NF- κ B (Auphan *et al.*, 1995; Scheinman *et al.*, 1995). Since transcription of many key inflammatory cytokines is regulated positively

by NF- κ B, induction of I κ B results in retention of NF- κ B in the cytosol and thus suppression of inflammatory cytokine production. Ligand-activated glucocorticoid receptors have also been found to physically interact with other transcription factors including AP-1 (Schule *et al.*, 1990) and NF- κ B (Ray and Prefontaine, 1994), to inhibit DNA binding and/or their transcriptional activity. Cross talk between the glucocorticoid receptor and other nuclear receptors may also play a role in mediating the effects of glucocorticoid ligands. Presently, it is believed that all of the above mechanisms contribute to the anti-inflammatory and immunosuppressive properties of glucocorticoids.

Therapeutic Agents

Historically speaking, very few drugs used today as immunosuppressive agents were actually developed for that purpose. In fact, if one looks closely enough, nearly all therapeutic agents possess some degree of immunomodulatory activity at some doses (Descotes, 1986). The recent explosion of knowledge regarding the function and regulation of the immune system (at the cellular, biochemical, and molecular levels) has provided investigators with a relatively new avenue for specific drug development. The following discussion focuses on those drugs used primarily for modulating the immune system: immunosuppressants (corticosteroids are described in the section "Natural and Synthetic Hormones"), AIDS therapeutics, biologics (ie, monoclonal antibodies, recombinant cytokines, and IFNs), and anti-inflammatory drugs.

Immunosuppressive Agents Several immunosuppressive drugs are efficacious simply due to their ability to impair cellular proliferation, since proliferation is required for lymphocyte clonal expansion and, subsequently, differentiation. Other drugs inhibit specific intracellular proteins that are critical in the activation of the immune response.

Originally developed as an antineoplastic agent, cyclophosphamide (Cytosan, CYP) is the prototypical member of a class of drugs known as alkylating agents. Upon entering the cell, the inactive drug is metabolically cleaved into phosphoramide mustard, a powerful DNA alkylating agent that leads to blockade of cell replication, and acrolein, a compound known to primarily bind to sulfhydryl groups. Clinically, CYP has found use in reducing symptoms of autoimmune disease and in the pretreatment of bone marrow transplant recipients. Experimentally, this drug is often used as a positive immunosuppressive control in immunotoxicology studies because it can suppress both humoral and CMI responses. There appears to be preferential suppression of B-cell responses, possibly due to decreased production and surface expression of Igs. CMI activities that are suppressed include the DTH response, CTL, graft-versus-host disease, and the MLR. Administration of low doses of CYP prior to antigenic stimulation can produce immune enhancement of cell-mediated and humoral immune responses, which has been attributed, in part, to an inhibition of suppressor T-cell activity (Limpens *et al.*, 1990; Limpens and Scheper, 1991). The immune-enhancing properties of CYP were demonstrated to be mediated by only one of the two major metabolites, acrolein, but not phosphoramide mustard (Kawabata and White, 1988).

Azathioprine (Imuran), one of the antimetabolite drugs, is a purine analog that is more potent than the prototype, 6-mercaptopurine, as an inhibitor of cell replication. Immune suppression likely occurs because of the ability of the drug to inhibit purine biosynthesis. It has found widespread use in the suppression of allograft rejection. It can also act as an anti-inflammatory drug and can reduce the number of neutrophils and monocytes. Clinical use of the drug is limited by bone marrow suppression and leukopenia.

Azathioprine inhibits humoral immunity, but secondary responses (IgG) appear more sensitive than primary responses (IgM). Several CMI activities are also reduced by azathioprine treatment, including DTH response, MLR, and graft-versus-host disease. Although T-cell functions are the primary targets for this drug, inhibition of NK function and macrophage activities has also been reported.

Leflunomide (Arava), an isoxazole derivative, is another agent that suppresses cellular proliferation, which has been used in the treatment of rheumatic disease and transplantation (Xiao *et al.*, 1994). Leflunomide inhibits *de novo* pathways of pyrimidine synthesis, thereby blocking progression from G₁ to S of the cell cycle. Thus, direct inhibition of B-cell proliferation may account for the drug's ability to inhibit both T-cell-dependent and T-cell-independent specific antibody production. Leflunomide can also directly inhibit T-cell proliferation induced by mitogens, anti-CD3, or IL-2.

Cyclosporin A (CsA, Sandimmune) is a cyclic undecapeptide isolated from fungal organisms found in the soil. Important to its use as an immunosuppressant is the relative lack of secondary toxicity (eg, myelotoxicity) at therapeutic concentrations (Calne *et al.*, 1981). However, hepatotoxicity and nephrotoxicity are limiting side effects. CsA acts preferentially on T cells by inhibiting the biochemical signaling pathway emanating from the TCR (reviewed by Ho *et al.*, 1996). The result is inhibition of IL-2 gene transcription and subsequent inhibition of T-cell proliferation and clonal expansion of effector T cells. More specifically, CsA interacts with the intracellular molecule cyclophilin, an intracellular protein with peptidyl proline isomerase activity (although this enzymatic activity has nothing to do with the immunosuppressive effect of CsA). The CsA–cyclophilin complex inhibits the serine/threonine phosphatase activity of a third molecule, calcineurin. The function of calcineurin is to dephosphorylate the cytoplasmic form of the transcription factor, NFAT, therefore facilitating the transport of NFAT into the nucleus, where it can couple with nuclear components and induce the transcription of the IL-2 gene. Inhibition of calcineurin phosphatase activity by the CsA–cyclophilin complex prevents nuclear translocation of NFAT and the resulting IL-2 gene transcription.

FK506 (Tacrolimus or Prograf) is a cyclic macrolide which is structurally distinct from CsA, but which possesses a nearly identical mechanism of action (reviewed by Ho *et al.*, 1996). Like CsA, FK506 binds intracellularly to proteins with peptidyl proline isomerase activity, the most abundant of which is FK506 binding protein-12 (FKBP12). The FK506–FKBP12 complex also binds to and inhibits calcineurin activity, thereby inhibiting IL-2 gene transcription. Clinically, FK506 inhibits T-cell proliferation, lacks myelotoxicity (although, like CsA, it does cause nephrotoxicity), and induces transplantation tolerance. In addition, the minimum effective dose appears to be approximately 10-fold lower than that of CsA.

Rapamycin (RAP, Sirolimus or Rapamune) is also a cyclic macrolide, which is structurally related to FK506. However, the mechanism by which it produces inhibition of proliferation is strikingly distinct. Unlike CsA and FK506, RAP does not inhibit TCR-dependent signaling events and IL-2 gene transcription. Rather, this compound inhibits IL-2-stimulated T-cell proliferation by blocking cell-cycle progression from late G₁ into S phase (Morice *et al.*, 1993; Terada *et al.*, 1993). Like FK506, RAP binds to the intracellular protein FKBP12. However, this RAP–FKBP12 complex does not bind calcineurin. Rather, the RAP–FKBP12 complex binds to the target of rapamycin, mTOR (Sabers *et al.*, 1995), inhibiting its function. Inhibition of mTOR results in reduced cell growth and suppression of cell cycle progression and proliferation (reviewed by Fingar and Blenis, 2004). Unlike both CsA and FK506, RAP does not appear to be nephrotoxic. Due to its mechanisms of action,

a significant advantage of RAP over CsA and FK506 is that it is an effective immune suppressant even after T cells have been activated, due to the fact that it blocks signaling through the IL-2 receptor. Conversely, for CsA and FK506 to be effective, T cells must encounter the drug prior to activation because once IL-2 transcription begins, neither therapeutic will provide effective suppression of the already activated T cells and IL-2 production.

AIDS Therapeutics Traditionally, antiviral therapies have not been extremely successful in their attempt to rid the host of viral infection. This may be due to the fact that these pathogens target the DNA of the host. Thus, eradication of the infection means killing infected cells, which for HIV, are primarily CD4⁺ T cells. Numerous strategies have been developed to combat HIV, including targeting viral reverse transcriptase (nucleoside and nonnucleoside reverse transcriptase inhibitors), viral protease, viral fusion and entry, virus–T-cell interaction proteins, and stimulating immune responses (reviewed by Broder, 2010). The multidrug therapy used currently is referred to as highly active antiretroviral therapy (HAART) (reviewed by Este and Cihlar, 2010). However, eradication of this virus, and subsequently AIDS, remains a challenge because the very nature of the infection has significant immunosuppressive consequences. In addition, some of the current therapies also exhibit immunosuppressive actions. One such antiviral drug is zidovudine (Retrovir).

Zidovudine (3'-azido-3'-deoxythymidine) is a pyrimidine analog that inhibits viral reverse transcriptase. It was the first drug shown to have any clinical efficacy in the treatment of HIV-1 infection. Unfortunately, its use is limited by myelotoxicity (macrocytic anemia and granulocytopenia) (Luster *et al.*, 1989). Early studies confirmed that the primary action of zidovudine is on innate immunity, although changes in both humoral immunity and CMI have also been observed (reviewed by Feola *et al.*, 2006). In addition, it was shown that oral administration of high doses of zidovudine caused thymic involution and decreased responsiveness of T cells to the HIV protein, gp120 (McKallip *et al.*, 1995). Clinically, zidovudine increases the number of circulating CD4⁺ cells and can transiently stimulate cell-mediated immune responses (lymphoproliferation, NK cell activity, and IFN- γ production). A final consideration for the immunotoxicity associated with AIDS therapeutics like zidovudine is that they are rarely administered alone and thus, drug interactions likely contribute to various immune effects.

Abacavir (ABC), a purine analog, is also an inhibitor of viral reverse transcriptase, but it has less adverse effects than zidovudine. However, in contrast to the immunosuppressive adverse effects of zidovudine, ABC induces hypersensitivity reactions in approximately 5% to 9% of patients initiating antiretroviral therapy with ABC. This adverse effect has been associated with the expression of the HLA haplotype HLA-B*5701 and elevated CD8⁺ CTL at the initiation of ABC treatment as well as an increase in CD8⁺ (not CD4⁺) T-cell proliferation in patients testing positive for ABC hypersensitivity (Easterbrook *et al.*, 2003; Phillips *et al.*, 2005). Based on these studies, a large study (1956 patients) was conducted to determine the effectiveness of prospective HLA-B*5701 screening in preventing hypersensitivity reactions to ABC (Mallal *et al.*, 2008). Screening eliminated hypersensitivity reactions to ABC, and the introduction of screening prior to therapy has made a hypersensitivity reaction to ABC a rare event.

Biologics Biologics refers to those therapies that are derived in some manner from living organisms and include monoclonal antibodies, recombinant proteins, and adoptive cell therapies. By its very nature, the immune system is often both the intended therapeutic target and unintended toxicological target of various

biologics. Overall, manifestations of toxicity may include exaggerated pharmacology, effects due to biochemical cross talk, and disruptions in immune regulation by cytokine networks. Monoclonal antibodies can bind normal as well as targeted tissues, and any foreign protein may elicit the production of neutralizing antibodies against the therapeutic protein (ie, the therapeutic protein may be immunogenic). While certainly many biologics are being utilized safely, the immunotoxicological aspects of a monoclonal antibody (anti-CD3), TNF blockers, and a recombinant protein (IFN- α) will be discussed.

Monoclonal antibodies have been designed in general to suppress immune function, and include antibodies directed against certain molecules that are critical for inducing or sustaining an immune response and can be divided into the following mechanistic categories: (1) bind and neutralize specific cytokines (TNF- α ; IL-6); (2) bind cell-surface molecules to trigger lysis by the adaptive immune response (CD3 on T cells; CD25, α subunit of IL-2 receptor; CD20 on mature B cells; CD52 on B cells, T cells, NK cells, monocytes, and macrophages); (3) bind cell-surface molecules and block costimulation signals from other cells (CD2 on T cells; CD80/CD86 on APCs, soluble BLYS/BAFF, CD40L on T cells); and (4) bind cell adhesion molecules and block lymphocyte trafficking (LFA-1 or $\alpha 4$ on leukocytes). Monoclonal antibodies directed against CD3 (Muromonab-CD3, OKT3), part of the TCR complex, have been used for acute transplant rejection. All T cells express CD3 and binding by anti-CD3 Ig opsonizes T cells for depletion by complement activation and immune clearance. Since CD3 is part of the TCR signaling complex, binding of OKT3 to CD3 can acutely induce a “cytokine release syndrome” due to a transient activation and release of cytokines, which soon after initial administration, flu-like symptoms, pulmonary edema, and hematological disorders have been reported (reviewed by Sgro, 1995). Anaphylactic reactions (Type I hypersensitivity) to the antibody can also occur. Additionally, OKT3 is a murine monoclonal antibody, therefore the therapeutic efficacy and duration of action may be decreased due to host recognition and clearance. The establishment of immunological memory will lead to more rapid clearance on subsequent administration.

Etanercept (Enbrel), adalimumab (Humira), and infliximab (Remicade) are disease-modifying antirheumatic drugs (DMARD) that block TNF to prevent (1) induction of other proinflammatory cytokines such as IL-1, IL-6, and IL-8; (2) macrophage and neutrophil activation; (3) fibroblast and endothelial activation; (4) induction of other acute-phase proteins; and (5) leukocyte migration to inflammation sites. Etanercept is a recombinant protein consisting of a dimer of the extracellular ligand-binding portion of the human 75 kD TNF receptor (TNFR2) fused to the Fc portion of human IgG1. Because TNFR2 is not selective, etanercept binds both circulating TNF- α and TNF- β preventing binding to the endogenous TNFR1 (55 kDa, TNF- α selective) and TNFR2 receptors. Adalimumab and infliximab, however, are recombinant monoclonal antibodies directed against TNF- α , which neutralize circulating TNF- α and prevent interaction with either TNFR1 or TNFR2. Hypersensitivity is a potential adverse effect of these drugs. Other immune-related adverse effects include opportunistic infections, malignancy, and autoimmune disorders which are a potential problem for all drugs that suppress the immune system. Of particular concern for TNF- α inhibitors is an association with a greater risk of tuberculosis; patients are now evaluated for tuberculosis risk factors and for latent tuberculosis infection prior to starting TNF- α inhibitor therapy (Toussirot and Wendling, 2007).

The majority of recombinant proteins have been used as immunostimulants, including IFN- α , IFN- γ , GM-CSF, erythropoietin,

IL-2, and IL-12. Recombinant proteins used as immunosuppressants include IL-1 receptor antagonist (IL-1RA) and the abovementioned etanercept which is a hybrid of the extracellular ligand-binding portion of TNFR2 fused to the Fc portion of human IgG1. IFN- α , which is used as an antiviral agent, is used to treat hepatitis C and other chronic viral illnesses. The mechanism of the antiviral action of IFN- α involves, in part, direct suppression of viral replication, activation of NK cells, and enhanced expression of MHC1 on virally infected cells thus increasing the likelihood of recognition by virus-specific T cells. Administration of IFN- α has been associated with autoimmune diseases, including autoimmune hypothyroidism and lupus (Vial and Descotes, 1995) and hematological disorders stemming from bone marrow suppression.

Anti-inflammatory Agents Anti-inflammatory agents include nonselective and selective nonsteroidal anti-inflammatory drugs (NSAIDs), which suppress the production of proinflammatory soluble factors, such as prostaglandins and thromboxanes. Nonselective NSAIDs are a large class of drugs that reversibly inhibit both isoforms of cyclooxygenase (COX-1 and COX-2). The COX-2 enzyme, in particular, is induced in response to inflammatory cytokines and mediators and therefore, represents an attractive target to combat inflammatory diseases. However, due to an increased risk of cardiovascular effects in some patients (reviewed by Grosser *et al.*, 2006), which is a side effect to varying degrees for all NSAIDs, the only COX-2 selective inhibitor currently approved for clinical use is celecoxib (celebrex). Aspirin, like nonselective NSAIDs, inhibits COX-1 and 2 enzymes, but inhibition is irreversible due to covalent binding of aspirin by acetylation to a serine residue in the COX enzyme. Aspirin is especially effective as an antiplatelet since platelets possess little biosynthesizing capacity and therefore, aspirin will inhibit COX for the life of the platelet (8–11 days).

Drugs of Abuse

Drug abuse is a social issue with extensive pathophysiological effects on the abuser. Drugs of abuse exhibit immunosuppressive actions, and in fact it has been suggested that in addition to the direct risk of HIV contraction via needle sharing or judgment lapses, abuse of some drugs has been associated with disease progression to AIDS (Rogers, 2011). Several classes of drugs will be discussed, including cannabinoids, opioids, cocaine, methamphetamine, and ethanol. Reports regarding the immune system effects of many of these drugs are often contradictory, so it should be noted that the mechanisms by which drugs of abuse suppress immune function might depend on the development of tolerance or addiction to the drugs; the immune, withdrawal, and pain status of the individual; and levels of endogenous molecules (ie, endorphins or endocannabinoids).

Cannabinoids Much attention has been focused on the immunomodulatory effects of the cannabinoids, which can be defined as plant-derived (ie, from the marijuana plant), synthetic, or endogenous. Therapeutically, the primary psychoactive congener of marijuana, Δ^9 -tetrahydrocannabinol, is approved for use as an antiemetic in patients undergoing cancer chemotherapy and as an appetite stimulant for cachexia associated with advanced AIDS disease. Cannabinoids have also recently been approved for use in the treatment of symptoms associated with autoimmune disease, such as multiple sclerosis (Lakhan and Rowland, 2009). In addition, several states in the United States have legalized marijuana for medical use thereby increasing its use (Joffe and Yancy, 2004).

The mechanism by which Δ^9 -tetrahydrocannabinol produces psychotropic effects is through a G protein-coupled cannabinoid

receptor, CB1 (Varvel *et al.*, 2005). Peripheral tissues also express CB1, in addition to a second cannabinoid receptor, CB2. Although both receptors are expressed on immune system cells and are coupled to suppression of adenylate cyclase activity (Schatz *et al.*, 1997), it is not entirely clear the extent to which the receptors and/or suppression of adenylate cyclase activity contributes to immune system effects by cannabinoids.

Many studies have shown that exposure to Δ^9 -tetrahydrocannabinol decreases host resistance to bacterial and viral pathogens (reviewed by Cabral and Staab, 2005). Cannabinoids alter both humoral and CMI responses as evidenced by suppression of the T-cell-dependent AFC response both in vivo and in vitro (Schatz *et al.*, 1993) and direct suppression of T-cell function (Condie *et al.*, 1996). With respect to the mechanism of T-cell suppression, many plant-derived compounds suppress IL-2 at the transcriptional level which is due, in part, to suppression of transcription factor activation (AP-1, NFAT, NF- κ B) and ERK MAPK activity (Condie *et al.*, 1996; Faubert and Kaminski, 2000; Herring *et al.*, 1998). Although both cannabinoid receptors are expressed on T cells (Galiegue *et al.*, 1995), many of the direct T-cell effects of cannabinoids have been demonstrated to occur independently of either cannabinoid receptor (Kaplan *et al.*, 2003). On the other hand, B-cell suppression by Δ^9 -tetrahydrocannabinol was CB1 and/or CB2 receptor-dependent (Springs *et al.*, 2008).

Cannabinoid suppression of other APC, such as macrophages and DCs, is also mediated through the CB1 and/or CB2 receptors. Δ^9 -Tetrahydrocannabinol exposure impaired lysosomal or cytochrome *c* processing in macrophages (Matveyeva *et al.*, 2000; McCoy *et al.*, 1995) likely via the CB2 receptor (Buckley *et al.*, 2000; Chuchawankul *et al.*, 2004). IL-12 production from DC and subsequent Th1 activation was suppressed by Δ^9 -tetrahydrocannabinol in a CB1 and/or CB2 receptor-dependent manner (Lu *et al.*, 2006a, b). Taken together, these studies demonstrate that cannabinoid compounds alter immune function, and the mechanisms involve both cannabinoid receptor-dependent and -independent actions.

Opioids Similar to cannabinoids, opioids refer to plant-derived, synthetic, or endogenous (endorphins) compounds that bind opioid receptors. Although technically “opioid” refers to drugs derived from the poppy plant, and “opiate” refers to agonists and antagonists with morphine-like activity (including plant-derived and synthetic compounds), they are often used interchangeably. It is well established that opioids suppress immune responses and the mechanism often involves one of the G_i-coupled opioid receptors (μ , κ , and δ receptors), but there are opioid receptor-independent mechanisms as well (Roy *et al.*, 2011).

Early studies evaluating the immune competence of heroin addicts revealed a decrease in total T cells, which was reversed with the general opioid receptor antagonist, naloxone, suggesting a role for an opioid receptor in mediating immune suppression (McDonough *et al.*, 1980). Later studies demonstrated that although morphine suppressed several immune parameters, there was no dose–response, suggesting that the effects were not receptor mediated, but were the result of increased circulating corticosteroids (which were significantly elevated in those animals) (LeVier *et al.*, 1994). This conclusion is supported by the findings of other investigators as well (Pruett *et al.*, 1992b).

Several investigators have reported decreased host resistance to viral and bacterial infections in opioid-treated animals or heroin addicts. In one study, morphine treatment of mice infected with *S. pneumoniae* demonstrated increased bacterial burden in the lungs and increased mortality. The mechanism by which the

immune response was compromised involved, in part, suppression of NF- κ B gene transcription, which likely contributes to decreased expression of inflammatory mediators, such as chemokines, reducing recruitment of neutrophils to the infection site (Wang *et al.*, 2005a). There is also evidence that opioid use increases susceptibility to HIV infection. Although morphine and/or heroin use is associated with risk of HIV infection through shared needles, opioid use may contribute to progression of AIDS through immune suppression. Specifically, there is evidence that morphine treatment increases CCR5 expression, which is a primary receptor for HIV entry into macrophages (Guo *et al.*, 2002). In addition, chronic morphine treatment shifts the T-cell balance toward Th2 (Azarang *et al.*, 2007; Roy *et al.*, 2004). Further evidence for compromised immunity toward HIV is the observation that morphine inhibited anti-HIV activity in CD8⁺ cells in an opioid receptor-dependent manner (Wang *et al.*, 2005b).

Opioids also modulate innate immunity. Consistent with the observations that morphine and/or heroin use contributes to the progression of AIDS, Kupffer cells infected with HIV maintained in vitro in the presence of morphine resulted in a higher number of viral particles relative to untreated HIV-infected cells (Schweitzer *et al.*, 1991). More recent studies demonstrate either suppression (Sacerdote, 2003) or enhancement (Peng *et al.*, 2000) of cytokine production from macrophages. The differences might be due to the agonist used, in vitro versus in vivo administration, and the dosing regimen (ie, whether tolerance was induced or not). Overall, it is clear that opioids suppress immune function and that the mechanism by which this occurs is complex and likely involves the CNS, the autonomic nervous system, the hypothalamic–pituitary–adrenal axis, and one or more opioid receptors (Alonzo and Bayer, 2002).

Cocaine Cocaine is a potent local anesthetic and central nervous system stimulant. This drug and its derivatives have been shown to alter several measures of immune competence, including humoral and cell-mediated immune responses and host resistance (Watson *et al.*, 1983; Ou *et al.*, 1989; Starec *et al.*, 1991). Jeong *et al.* (1996) evaluated the effect of acute in vivo cocaine exposure on the generation of the anti-sRBC AFC, and determined that immune suppression was due to a cytochrome P450 metabolite of cocaine. Further studies demonstrated that sex, strain, and age differences can be detected in cocaine-induced immunomodulation as assessed by the anti-SRBC AFC response (Matulka *et al.*, 1996). Similar to other immunotoxic agents, the mechanism by which cocaine alters immune function involves a disruption of the Th1/Th2 balance and the stress response (Jankowski *et al.*, 2010; Stanulis *et al.*, 1997a, b). Cocaine also induces the secretion of TGF- β , which has been linked to the observation that cocaine exposure enhances replication of the HIV-1 virus in human PBMC (Chao *et al.*, 1991; Peterson *et al.*, 1991). A proteomic analysis was conducted in human DCs treated ex vivo with cocaine for 48 hours and demonstrated increased expression of NF- κ B (Reynolds *et al.*, 2009b), which could contribute to increased expression of various cytokines or chemokines. Cocaine was demonstrated to cause an increased HIV viral burden in a human PBL-SCID animal model, which was mediated through sigma 1 (σ 1) receptors, which are informally referred to as psychoactive drug receptors (Roth *et al.*, 2005). Although the function and role of σ 1 receptors still remain to be elucidated, additional studies also suggest that cocaine effects are mediated through these receptors (Cabral, 2006; Maurice and Romieu, 2004).

Methamphetamine Methamphetamine is a stimulant that is similar to amphetamine, although highly addictive and its use has been growing over the past several years. Relatively recently,

the immunotoxicity of methamphetamine was explored (In *et al.*, 2005). Following oral administration to mice, methamphetamine suppressed the anti-sRBC AFC response, IgG production, and mitogenic stimulation of T-cell proliferation. Even more striking was the suppression of GM-CSF-stimulated bone marrow colony growth by methamphetamine. These results indicate suppression of both CMI and humoral immunity *in vivo* following methamphetamine administration.

In human T cells, methamphetamine treatment *ex vivo* induced ROS and increased intracellular calcium (Potula *et al.*, 2010). Consistent with this, *ex vivo* treatment of human DCs with methamphetamine induced MEK, which activate MAPKs (Reynolds *et al.*, 2009a). Both of these studies demonstrate that in the absence of immune stimulation, acute methamphetamine treatment causes biochemical changes consistent with cellular activation. On the other hand, in mice treated *in vivo* with methamphetamine or in methamphetamine-using patients, plasma IL-6 was suppressed and IL-10 was increased, suggesting immune suppression following chronic methamphetamine use (Loftis *et al.*, 2011).

Ethanol Ethanol exposure has been studied both in alcoholic patients and in animal models of binge drinking. In humans, alcoholism is associated with an increased incidence of, and mortality from, pulmonary infection (reviewed by Happel and Nelson, 2005). There is also an increased incidence of bacterial infection and spontaneous bacteremia in alcoholics with cirrhosis of the liver (reviewed by Leevy and Elbeshbeshy, 2005). A consistent finding in abusers of ethanol is the significant change in PBMC. In animal models, this is observed as depletion of T and B cells in the spleen and the T cells in the thymus, particularly CD4⁺/CD8⁺ cells. The latter effect may be related in part to increased levels of corticosteroids, particularly in females (Glover *et al.*, 2011; Han *et al.*, 1993). In a binge-drinking animal model, ethanol suppresses innate immunity through impairment of TLR3 signaling in peritoneal macrophages. The authors also demonstrated suppression of proinflammatory cytokines (Pruett *et al.*, 2004b). In addition to suppression of TLR3, ethanol suppresses signaling through other TLRs, contributing to pleiotropic effects of ethanol on innate immunity (Pruett *et al.*, 2004a). Moreover, signaling alterations via TLRs depend on whether the alcohol exposure is acute or chronic (Dai and Pruett, 2006).

Inhaled Substances

Pulmonary defenses against inhaled gases and particulates are dependent on both physical and immunological mechanisms. Immune mechanisms primarily involve the complex interactions between neutrophils and alveolar macrophages and their abilities to phagocytize foreign material and produce cytokines, which not only act as local inflammatory mediators, but also serve to attract other cells into the airways.

Oxidant Gases It is clear that exposure to oxidant gases—such as ozone (O₃), sulfur dioxide (SO₂), nitrogen dioxide (NO₂), and phosgene—alters pulmonary immunological responses and might increase the susceptibility of the host to bacterial infections (reviewed by Selgrade and Gilmour, 1994). Infiltration of both neutrophils and macrophages has been observed, resulting in the release of cellular enzyme components and free radicals, which contribute to pulmonary inflammation, edema, and vascular changes. Exposure to O₃ has been demonstrated to impair the phagocytic function of alveolar macrophages and to inhibit the clearance of bacteria from the lung. These changes were correlated with decreased resistance to *S. zooepidemicus* and suggest

that other extracellular bacteriostatic factors may be impaired following exposure to these oxidant gases. Short-term NO₂ exposure decreases killing of several bacterial pathogens and, like O₃, this decreased resistance is probably related to changes in pulmonary macrophage function. A role for the products of arachidonic acid metabolism (specifically, the prostaglandins) has recently been implied and is supported by the fact that decreased macrophage function is associated with increased PGE₂ production and that pretreatment with indomethacin inhibits O₃-induced pulmonary hyperresponsiveness and related inflammatory responses. In humans, O₃ challenge produced a decrease in the number of macrophages in airway sputum; however, the recovered macrophages exhibited evidence of activation and enhanced antigen-presenting capability as demonstrated by increased CD80, CD86, and HLA-DR (Lay *et al.*, 2007). In controlled studies, allergic asthmatic volunteers challenged with O₃ were found to have increased levels of inflammatory cytokines, IL-1β and IL-6, while levels of the anti-inflammatory cytokine, IL-10, were decreased in airway sputum. O₃ has also been associated with increased airway neutrophilia and eosinophilia (Peden, 2011).

It is clear that exposure to oxidant gases can also augment pulmonary allergic reactions. This may be a result of increased lung permeability (leading to greater dispersion of the antigen) and to the enhanced influx of antigen-specific IgE-producing cells in the lungs. In studies involving O₃ exposure and challenge with *L. monocytogenes*, decreased resistance to the pathogen correlated not only with changes in macrophage activity, but also with alterations in T-cell-derived cytokine production (which enhances phagocytosis). In support of an effect on T cells, other cell-mediated changes were observed including changes in the T- to B-cell ratio in the lung, decreased DTH response, enhanced allergic responses, and changes in T-cell proliferative responses.

Particles: Asbestos, Silica, and nanoparticles It is believed that alterations in both humoral immunity and CMI occur in individuals exposed to asbestos and exhibiting asbestosis. Decreased DTH response and fewer T cells circulating in the periphery as well as decreased T-cell proliferative responses have been reported to be associated with asbestosis (reviewed by Miller and Brown, 1985; Warheit and Hesterberg, 1994). Autoantibodies and increased serum Ig levels have also been observed. Within the lung, alveolar macrophage activity has been implicated as playing a significant role in asbestos-induced changes in immune competence. Fibers of asbestos that are deposited in the lung are phagocytized by macrophages, resulting in macrophage lysis and release of lysosomal enzymes and subsequent activation of other macrophages. It has been hypothesized that the development of asbestosis in animal models occurs by the following mechanism: fibers of asbestos deposited in the alveolar space recruit macrophages to the site of deposition. Some fibers may migrate to the interstitial space where the complement cascade becomes activated, releasing C5a, a potent macrophage activator and chemoattractant for other inflammatory cells. Recruited interstitial and resident alveolar macrophages phagocytize the fibers and release cytokines, which cause the proliferation of cells within the lung and the release of collagen. A sustained inflammatory response could then contribute to the progressive pattern of fibrosis, which is associated with asbestos exposure.

The primary adverse consequence of silica exposure, like that to asbestos, is the induction of lung fibrosis (silicosis). However, several immune alterations have been associated with silica exposure in experimental animals, including decreased antibody-mediated and CMI parameters (reviewed by IPCS, 1996). Alterations

in both T- and B-cell parameters have been reported, although T-cell-dependent responses appear to be more affected than B-cell-dependent responses. Dose and route of antigen exposure appear to be important factors in determining silica-induced immunomodulation. Silica is toxic to macrophages and neutrophils, and exposure is correlated with increased susceptibility to infectious pathogens. The significance of these immunological alterations for the pathogenesis of silicosis remains to be determined. The association of this disease with the induction of autoantibodies is discussed in the subsection “Silica” under “Xenobiotic-Induced Hypersensitivity and Autoimmunity.”

More recently, there has been growing interest in the effects of nanomaterials, especially airborne nanoparticles on lung-related diseases and the role of the immune system in the etiology of these diseases. The term “nanomaterial” is extremely broad and only signifies that the material is less than 100 nm in size. Among these nanomaterials, nanosized silicas are members. Although much is known concerning the toxicity of crystalline silica, little is known about the toxicity of nanosized silicas, as is the case for the majority of other nanosized materials. Significant effort is currently being directed toward understanding the influence of shape, charge, composition, specific functional groups, catalytic activity, and other properties on the biological and toxicological potential of these nanomaterials. In more recent studies, it has been reported that airway exposure to nanoparticles can induce a number of proinflammatory cytokines including IL-1 β , MCP-1, MIP-2, GM-CSF, and MIP-1 α . The mechanism by which exposure to nanoparticles results in induction of proinflammatory cytokines is presently poorly understood, but is believed, in part, to involve induction of oxidative stress (Di Gioacchino *et al.*, 2011) and, in part, through the activation of the NALP3-inflammasome (Martinon *et al.*, 2009). The NALP3-inflammasome is a cytosolic multiprotein complex, which when activated promotes the production of inflammatory cytokines (Fig. 12-22). In fact, pulmonary inflammation is a common response induced by nanoparticles in airways that cannot be explained by their surface chemistry and composition (Sager *et al.*, 2008). A concern with exposure to nanoparticles is the possibility they can enhance immune responses to airborne antigens due to their ability to induce pulmonary inflammation. Indeed, several recent studies have demonstrated with a number of different

nanoparticles, including multiwalled carbon nanotubes and titanium oxide, that when administered to experimental animals in combination with ovalbumin, the inflammatory and immunological responses, as measured by cytokine production, cellular infiltrate, and ovalbumin-specific antibodies, were significantly increased when compared to ovalbumin alone (Larsen *et al.*, 2010; Ryman-Rasmussen *et al.*, 2009). Exposure to nanoparticles can occur in the occupational setting, or through environmental exposure to ultra-fine particles, which are, for example, by-products of combustion engines and common constituents of urban air pollutants. Further investigation is needed to understand the risks associated with exposure to nanoparticles, especially on respiratory disease.

Pulmonary Irritants Chemicals such as formaldehyde, silica, and ethylenediamine have been classified as pulmonary irritants and may produce hypersensitivity-like reactions. Macrophages from mice exposed to formaldehyde vapor exhibit increased synthesis of hydroperoxide (Dean *et al.*, 1984). This may contribute to enhanced bactericidal activity and potential damage to local tissues. Although silica is usually thought of for its potential to induce silicosis in the lung (a condition similar to asbestosis), its immunomodulatory effects have also been documented (Levy and Wheelock, 1975). Silica decreased reticuloendothelial system clearance and suppressed both humoral immunity (AFC response) and the CMI response (CTL) against allogeneic fibroblasts. Both local and serum factors were found to play a role in silica-induced alterations in T-cell proliferation. Silica exposure may also inhibit phagocytosis of bacterial antigens (related to reticuloendothelial system clearance) and inhibit tumoricidal activity (Thurmond and Dean, 1988).

Ultraviolet Radiation

Ultraviolet radiation (UVR), especially midrange UVB (290–340 nm), is an important environmental factor affecting human health with both beneficial effects including vitamin D production, tanning, and adaptation to UV, and adverse effects including sunburn, skin cancer, and ocular damage. Most, if not all of the chemicals, drugs and other materials discussed in this chapter were selected because they have been associated with immunotoxic effects, and because there is the chance for human exposure. And indeed, UVR has also been demonstrated to modulate immune responses in animals and humans. In fact, UVR is cited elsewhere in this chapter as one of the examples of where the parallelogram approach has been effectively used for a human risk assessment (van Loveren *et al.*, 1995). It is important to emphasize that all humans encounter lifetime exposure to this ubiquitous environmental immunotoxicant (Ullrich, 2007a). The effects of UV exposure on the immune system have been reviewed (Garssen and van Loveren, 2001). While UV-induced immunomodulation has been shown to have some beneficial effects on some skin diseases, such as psoriasis, and has been demonstrated to impair some allergic and autoimmune diseases in both animals and humans, UV-induced immunomodulation can also lead to several adverse health consequences, including a pivotal role during the process of skin carcinogenesis. Kripke (1981) provided the first evidence that UVR was immunosuppressive. UV-induced skin tumors were removed and transplanted into normal age- and sex-matched syngeneic recipient mice. Interestingly, the tumors did not grow in normal mice, and progressive tumor growth was only seen when the tumors were transplanted into recipient mice that were immunosuppressed. These results were explained by proposing that exposure to UVR had two effects: induction of skin tumors and induction of immune suppression. Studies have shown that these two events are related

Figure 12-22. Activation of the inflammasome by nanomaterials. Nanomaterials can be adjuvants through effects in APCs. For example, in a macrophage, nanomaterials can induce reactive oxygen species (ROS) to enhance expression of MHCII or B7 proteins or activate the inflammasome. Upon activation, the inflammasome produces active IL-1 β and IL-18, which can recruit other monocytes or DCs, or enhance T-cell proliferation.

(Ullrich, 2007b) based on a series of observations. First, UVR-induced keratinocyte-derived platelet activating factor was shown to play a role in the induction of immunosuppression. Second, *cis*-urocanic acid, a skin-derived immunosuppressive compound, mediates immune suppression by binding to serotonin receptors on target cells. Finally, studies showed that blocking the binding of these compounds to their receptors not only suppresses UVR-induced immune suppression, but that this approach also interferes with skin cancer induction.

There have been a number of studies to further characterize the mechanism of action for UV-induced immunomodulation. The first step is the absorption of UV photons by chromophores, so-called “photoreceptors,” such as DNA and urocanic acid (Garssen *et al.*, 1997). As a consequence of UV absorption by chromophores, epidermal and dermal cells, including keratinocytes, melanocytes, Langerhan’s cells, mast cells, dermal fibroblasts, endothelial cells, as well as skin-infiltrating cells (ie, granulocytes and macrophages), produce and/or release many immunoregulatory mediators, including cytokine, chemokines, and neurohormones (Sleijffers *et al.*, 2004). The mediators include both pro- and anti-inflammatory cytokines, such as TNF- α , IL-1, IL-6, and IL-10, which can modify directly or indirectly the function of APCs. Langerhan’s cells, the major APC in the skin, change phenotypically and functionally, which ultimately impacts the activity of T cells at the time of antigen presentation, both locally and systemically. One early explanation for UV-induced immunomodulation is that UVR induced a switch from a predominantly Th1 response (favoring DTH responses) to a Th2 response (favoring antibody responses). This hypothesis was supported by findings of altered cytokine secretion patterns indicative of a Th1 to Th2 switch (Araneo *et al.*, 1989; Simon *et al.*, 1990). Indeed, the majority of studies dealing with the effects of UVR indicated that Th1-mediated immune responses are especially sensitive to UV exposure. However, as noted above, UVR has been demonstrated to be associated with a suppression of certain allergic and autoimmune reactions. Indeed, more recent studies have demonstrated that Ig isotypes that are linked to either Th1 or Th2 cells can be suppressed by UVR and that UV exposure not only impairs Th1 responses; but also some Th2 responses (Sleijffers *et al.*, 2004).

Schwartz (2008) summarized 25 years of studies by noting that in contrast to the general immunosuppression associated with the use of conventional immunosuppressive drugs, UVR suppresses the immune system in an antigen-specific fashion via the induction of immunotolerance. Several investigators have noted that this effect is mostly mediated via Tregs induced by UVR, and that induction of Tregs, expressing CD4 and CD25, is an active process, which requires antigen presentation by UV damage. Once activated in an antigen-specific manner, these Tregs can suppress immune responses in a general fashion via the release of IL-10. Ullrich (2007a) noted that this model is consistent with the fact that UVR is absorbed in the upper layers of the skin, does not penetrate into the underlying tissues and internal organs, and that T cells are not directly targeted by UVR *in vivo* because few T cells are found in normal skin.

XENOBIOTIC-INDUCED HYPERSENSITIVITY AND AUTOIMMUNITY

When an individual’s immune system responds in a manner producing tissue damage, it could result in hypersensitivity or autoimmunity, which could be exacerbated, or even induced by, a xenobiotic.

Fig. 12-23 is a schematic delineating the possible cascade of effects that can occur when a chemical produces an immune-mediated disease.

Hypersensitivity

Polyisocyanates Polyisocyanates have a widespread use in industry and are responsible for occupationally related lung disease. These chemicals are used in the production of adhesives, paint hardeners, elastomers, and coatings. Occupational exposure is by inhalation and skin contact. Polyisocyanates are known to induce all four types of hypersensitivity responses.

Compounds in this group include toluene diisocyanate, methylene diphenyl diisocyanate, and hexamethylene diisocyanate. They are highly reactive compounds that readily conjugate with endogenous proteins, such as albumin, forming neoantigens responsible for hypersensitivity (Wisnewski *et al.*, 2011). Pulmonary sensitization to these compounds can occur through either topical or inhalation exposure. In murine models employing intranasal or intratracheal sensitization and challenge with toluene diisocyanate, significant induction of Th2 cytokines, IgE, and eosinophilia has been demonstrated (Ban *et al.*, 2006; Matheson *et al.*, 2005; Plitnick *et al.*, 2005). It has also been demonstrated that albumin-conjugated methylene diphenyl diisocyanate challenge via intranasal instillation following initial dermal exposure caused increased airway inflammation as characterized by eosinophil and lymphocyte infiltration into the BALF (Wisnewski *et al.*, 2011).

In humans diagnosed with occupational asthma associated with diisocyanate exposure, there was increased production of IL-8, MCP-1, TNF- α , and RANTES (chemokine ligand CCL5) in PBMC stimulated *ex vivo* with albumin-conjugated diisocyanate (Lumms *et al.*, 1998). Moreover, an examination of humans exposed to various diisocyanates demonstrated an association between incidence of occupational asthma from hexamethylene diisocyanate and specific SNPs in genes encoding IL-4 receptor α , IL-13, and CD14 (Bernstein *et al.*, 2006, 2011). It has also been shown that diisocyanate-induced IgE is not as robust as that observed in allergic asthma, suggesting that distinct pathophysiological mechanisms control occupational versus allergic asthma (Bernstein *et al.*, 2002). In a mouse model in which toluene diisocyanate plus ovalbumin was used to induce asthma, PI3 kinase was critical for the upregulation of IL-17 and pulmonary inflammation (Kim *et al.*, 2007). The mechanism by which cytokines and chemokines are upregulated also likely involves activation of p38 MAPK (Mitjans *et al.*, 2008).

Acid Anhydrides The acid anhydrides are reactive organic compounds used in the manufacturing of paints, varnishes, coating materials, adhesives, and casting and sealing materials. Trimellitic acid anhydride (TMA) is one of the most widely used compounds in this group, and it causes all four hypersensitivity reactions. Similar to the diisocyanates, acid anhydrides bind to serum proteins, such as albumin (Valstar *et al.*, 2006).

In an attempt to understand mechanisms by which TMA induced asthma following occupational exposure, a comparison between topical versus intranasal sensitization with TMA was conducted (Farraj *et al.*, 2006). Intranasal challenge with TMA in mice that were either topically or intranasally sensitized with TMA produced a marked allergic rhinitis of similar severity, characterized by an influx of eosinophils and lymphocytes. Both the topical and intranasal routes of sensitization also produced significant increases in total serum IgE after intranasal challenge with TMA. In addition, both the topical and intranasal routes of sensitization induced significant increases in the mRNA expression of the Th2 cytokines IL-4, IL-5, and IL-13 (Farraj *et al.*, 2006). These findings are significant

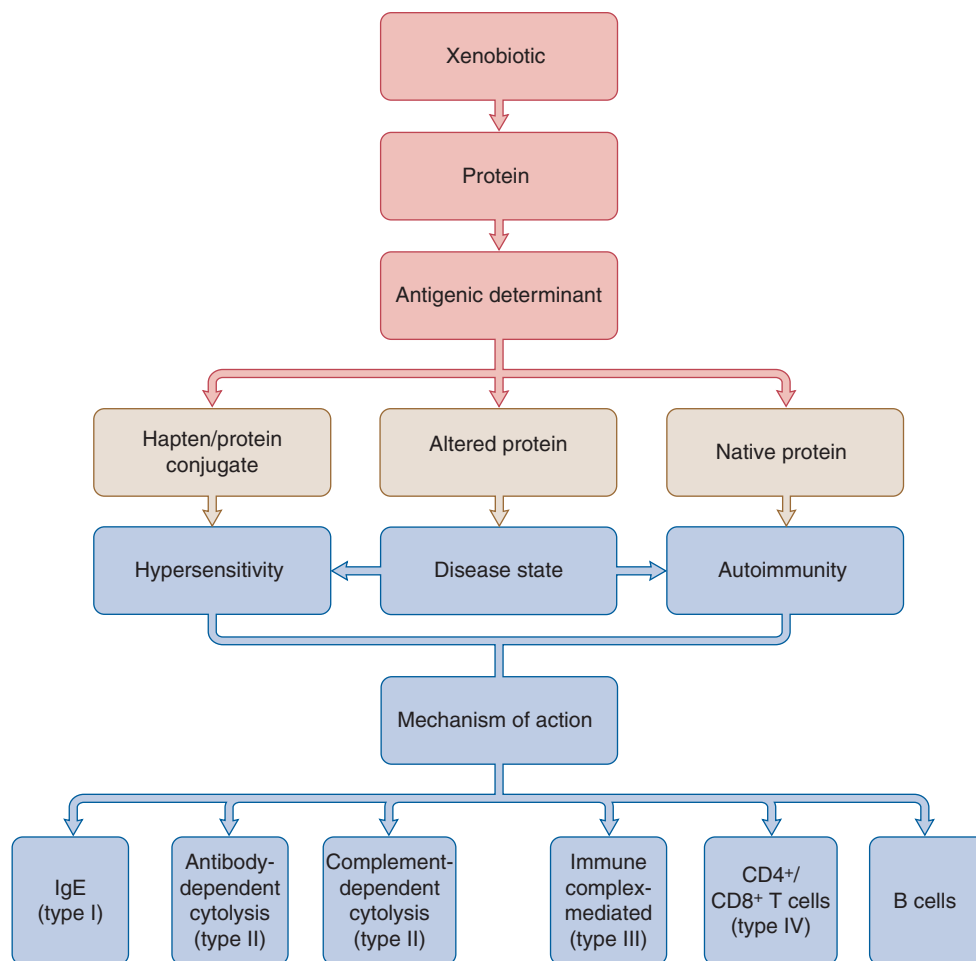

Figure 12-23. Schematic diagram of xenobiotic induction of hypersensitivity or autoimmunity. The mechanisms by which xenobiotics induce hypersensitivity or autoimmunity can overlap, although IgE production is most often associated with hypersensitivity.

as they suggest that dermal exposure represents a potential route of sensitization of the respiratory tract to chemical allergens.

Toxicogenomic analyses have been conducted in an attempt to identify gene expression profiles for TMA-induced occupational asthma and/or contact dermatitis (Regal *et al.*, 2007). In one study, although overlap between genes induced in response to ovalbumin (allergic asthma model) or TMA (occupational asthma model) in mice occurred, over 100 unique TMA-induced genes were identified (Regal *et al.*, 2007). Another study examined the gene expression profile in auricular lymph nodes following dermal exposure to TMA to determine changes in gene expression that correlated with the LLNA (Boverhof *et al.*, 2009). Over 1000 genes were expressed in response to the highest dose of TMA following dermal exposure, including IL-4, IL-21, Mki67 (involved in cell division), and Aicda (involved in B cell class switch recombination) (Boverhof *et al.*, 2009).

Cellular assays are also being developed to identify respiratory sensitizers, particularly to determine if low dose exposures contribute to occupational asthma. For instance, in response to a low dose of intratracheal administration of TMA, IgE⁺ and MHCII⁺ B cells were identified in the lung-associated lymph nodes (Fukuyama *et al.*, 2010). The increase in IgE⁺MHCII⁺ B cells correlated with increased serum and BALF IgE and IgG1, and increased inflammatory cells in the BALF (eosinophils, neutrophils) (Fukuyama *et al.*, 2010).

Metals Metals and metallic substances, including metallic salts and metal-containing nanomaterials, are responsible for producing

contact and pulmonary hypersensitivity reactions. For additional information on the mechanisms by which metal-containing nanomaterials induce hypersensitivity, the reader is referred to “Chap. 28, Nanotoxicology.” Exposure to these compounds may occur via inhalation or due to their solubility in aqueous media. Although many metals induce contact dermatitis (Forte *et al.*, 2008), platinum, cobalt, chromium, nickel, and beryllium will be discussed here.

Platinum Exposure to platinum-group elements occurs occupationally in the mining, dentistry, and jewelry industries. There may also be acute hypersensitivity to platinum-containing chemotherapeutics in up to 20% of patients (Syrigou *et al.*, 2010). Platinum salts are allergenic and induce Type I and IV hypersensitivity reactions such as contact dermatitis and occupational asthma.

Exposure to the platinum salt sodium hexachloroplatinate by intradermal sensitization followed by intranasal challenge as a model of platinum-induced occupational asthma demonstrated that IL-4, IL-5, and IL-13 were modestly induced following *ex vivo* stimulation of lung-associated lymph nodes with Con A (Ban *et al.*, 2010). Serum IgE levels and BALF neutrophils and eosinophils were also increased. These results are consistent with increased IgE in peripheral blood of platinum-sensitized patients (Raulf-Heimsoth *et al.*, 2000).

Cobalt Cobalt exposure comes from metal-on-metal replacement prostheses, or occupationally in superalloy production and pigment manufacturing. Cobalt also induces Type I and IV hypersensitivity reactions such as contact dermatitis, DTH in peri-implant areas in

hip replacement patients, and occupational asthma (Thyssen and Menne, 2010).

There are several studies in which hip replacement patients who received metal-on-metal arthroplasty had increased metal-reactive T-cell responses. In one study, 7 out of 16 hip replacement patients demonstrated skin reactivity to cobalt, and of those 7 patients, 3 had elevated serum IgE (Thomas *et al.*, 2009). Moreover, PBMC from 7 out of 16 patients proliferated *ex vivo* in response to cobalt chloride stimulation (Thomas *et al.*, 2009). Part of this mechanism might involve creation of metal-protein complexes, which act as haptens (Mabilleau *et al.*, 2008).

In workers exposed to hard metal dust (a cobalt-containing alloy), there was increased incidence of asthma and higher serum IgE levels (Shirakawa *et al.*, 1992), indicating cobalt-induced occupational asthma. In a mouse model in which control or hypoxia inducible factor-1 α (HIF-1 α) was postnatally deleted in the lung, oropharyngeal aspiration of cobalt chloride induced a robust Th2-mediated asthma-like response characterized by eosinophilia, mucus cell metaplasia, and altered cytokine profile (Saini *et al.*, 2010a, b). These results suggest that hypoxia signaling via HIF-1 α might contribute to cobalt-induced occupational asthma.

Chromium Chromium is another metal in which exposure occurs either from metal-on-metal prosthesis, or occupationally in the electroplating, leather tanning, and paint, cement, and paper pulp production industries. Chromium predominantly elicits contact dermatitis (Shelnutt *et al.*, 2007), a Type IV hypersensitivity reaction, but can also induce hypersensitivity in patients with metal-on-metal hip arthroplasty, similar to those observed in response to cobalt (Thomas *et al.*, 2009). Chromium exists in several oxidation states, including chromium (III) or chromium (VI), but chromium (VI) more readily permeates the skin barrier (Forte *et al.*, 2008). However, once absorbed, chromium (VI) is reduced to chromium (III), which is most likely responsible for chromium toxicity (Shelnutt *et al.*, 2007).

Upon the reduction of chromium (VI) to chromium (III), ROS are produced. Production of ROS is one mechanism by which hypersensitivity reactions are exacerbated (Roychowdhury and Svensson, 2005). Indeed, chromium has been shown to increase ROS production in several cell types. In human dermal fibroblasts treated with potassium dichromate, heme oxygenase-1 expression (HMO-1) was induced in a MAPK-dependent manner (Joseph *et al.*, 2008). Similarly, in a HaCT keratinocyte cell line, potassium dichromate increased ROS formation, and activated Akt, NF- κ B, and MAPK, ultimately contributing to the induction of IL-1 α and TNF- α (Wang *et al.*, 2010).

Nickel Exposure to nickel occupationally occurs in the mining, milling, smelting, and refinishing industries. Consumers are exposed through clothing fasteners or body piercings, with adult women having the highest prevalence of nickel allergy (up to 17%) (Thyssen and Menne, 2010). Nickel causes both Type I and IV hypersensitivity. Similar to chromium, higher oxidation states of nickel have greater potential to sensitize individuals (Kasper-Sonnenberg *et al.*, 2011), which could also be due to higher potential to generate ROS when reduced *in vivo*.

Most people are sensitized to nickel dermally; however, there have been reports that exposure of children to relatively high ambient air nickel concentrations was associated with a positive skin test for nickel (Kasper-Sonnenberg *et al.*, 2011). Nickel sulfate treatment of human DC isolated from PBMC demonstrated robust induction of IL12, which was due to nickel sulfate activation of NF- κ B, p38 MAPK, and IFN regulatory factor-1 (IRF-1) (Antonios *et al.*, 2010). Induction of IL-12 helps to stimulate T cells and in

fact, nickel-reactive T cells can be isolated from PBMC of nickel-sensitized individuals (Moed *et al.*, 2004). However, a recent study demonstrated that nickel chloride treatment of purified CD3⁺ T cells activated with anti-CD3/CD28 impaired T-cell activation likely through inhibition of intracellular calcium concentration and NFAT activation (Saito *et al.*, 2011). The authors suggested that the discrepancy in T-cell effects by nickel is either due to differences in nickel concentrations and/or differences in the ability of nickel to target different transcription factors (Saito *et al.*, 2011).

Beryllium Beryllium exposure occurs most frequently in high-technology ceramics and dental alloy manufacturing, and in the electronics, nuclear, and aerospace industries. Although its use in the manufacturing of fluorescent bulbs has been discontinued, chronic beryllium disease (CBD) was originally identified in 1946 in a group of fluorescent lamp manufacturing workers (Forte *et al.*, 2008). Beryllium produces Type IV hypersensitivity reactions. Skin contact has been found to produce lesions of contact hypersensitivity, whereas lesions produced by penetration of splinters of beryllium under the skin are granulomatous in nature. Inhalation of beryllium can result in acute beryllium disease (ABD such as pneumonitis, tracheobronchitis), CBD, and increased risk of lung cancer (Cummings *et al.*, 2009; McCleskey *et al.*, 2009).

CBD is a pulmonary disease characterized by granulomas. Most patients with CBD also possess lymphocytes that proliferate in response to *ex vivo* beryllium treatment (Rosenman *et al.*, 2011). One possible mechanism for the sensitization and subsequent development of disease is that beryllium can alter peptide binding to MHC molecules. In fact, it has been reported that there is a glutamic acid substitution in one of the MHCII molecules in humans both sensitized to beryllium and those diagnosed with CBD, indicating a genetic susceptibility to beryllium-induced hypersensitivity (Rosenman *et al.*, 2011).

Therapeutic Agents Hypersensitivity responses to therapeutic drugs are among the major types of unpredictable drug reactions, accounting for up to 10% of all adverse effects. Drugs that commonly induce hypersensitivity include sulfa drugs, barbiturates, anticonvulsants, insulin, iodine (used in many X-ray contrast dyes), and platinum-containing chemotherapeutics. Penicillin is the most common agent involved in drug allergy and is discussed here as an example. The high incidence of allergic reaction to penicillin is in part due to widespread exposure to the compound. Not only has there been indiscriminant use of the drug, but exposure occurs through food products including milk from treated animals and the use of penicillin as an antimicrobial in the production of vaccines. Efforts are still being made to reduce unnecessary exposure.

The mechanism by which hypersensitivity to penicillin occurs is through the formation of a neoantigen. The formation of the primary penicillin neoantigen occurs during the breakdown of penicillin, in which the β -lactam ring opens, forming a reactive intermediate that reacts with other proteins. The resultant penicilloylated protein now acts as a hapten to which the immune system mounts a response. As is the case with other haptens, subsequent exposures to penicillin may not absolutely require the formation of penicilloylated proteins to elicit secondary responses.

Reactions to penicillin are varied and may include any of the four types of hypersensitivity reactions (reviewed by Chang *et al.*, 2011). The most commonly seen clinical manifestation of Type I reactions is urticaria; however, anaphylactic reactions occur in about 10 to 40 of every 100,000 patients receiving injections. Clinical signs of rhinitis and asthma are much less frequently observed. Blood dyscrasias can occur due to the production of IgG

against penicillin metabolites bound to the surface of red blood cells (Type II reaction). Penicillin has also been implicated in Type III reactions leading to serum-sickness-like symptoms. Owing to the high frequency of Type IV reactions when penicillin is applied topically, especially to inflamed or abraded skin, products are no longer available for topical application. Type IV reactions generally result in an eczematous skin reaction, but a rare, life-threatening form of dermal necrosis may result. In these cases, there is severe erythema and a separation of the epidermis at the basal layer. This reaction, which gives the clinical appearance of severe scalding, is thought to be a severe delayed reaction.

Latex Natural rubber latex is derived from the rubber tree *Hevea brasiliensis* and is used in the manufacture of over 40,000 products including examination and surgical gloves, among other medical products. Allergic reactions to natural rubber latex products have become an important occupational health concern with increased use of universal precautions, particularly latex gloves, to combat the spread of bloodborne pathogens. Hypersensitivity to latex usually occurs via a Type I or Type IV reaction. Dermatological reactions to latex include irritant dermatitis due to chemical additives or mechanical abrasion and the occlusive conditions caused by wearing gloves; contact dermatitis due to the chemical additives used in the glove manufacturing (eg, thiurams, carbamates, mercapto compounds, and phenylenediamines), and potentially more serious IgE-mediated responses due to residual latex proteins that remained in the finished products (reviewed by Shah and Chowdhury, 2011). The IgE responses may manifest as urticaria, asthma, or life-threatening anaphylaxis. Several latex proteins have been identified, and antibodies to most can be detected in latex-allergic individuals (Ahmed *et al.*, 2004; Lehto *et al.*, 2007).

Food and Genetically Modified Organisms Awareness of hypersensitivity reactions to foods and genetically modified organisms (or crops; GMOs) has increased in the last several years. The most common food allergens are milk, egg, peanuts and other tree nuts, fish, shellfish, soy, and wheat. Peanut allergies are relatively common, can be severe, thus, current information regarding the mechanism of peanut hypersensitivity is provided as an example. Hypersensitivity to peanuts occurs primarily via a Type I reaction, and the IgE responses may include shortness of breath, asthma, and anaphylaxis. At least 11 peanut proteins have been identified and antibodies to most can be detected in peanut-allergic patients (reviewed by Finkelman, 2010). More recent studies have shown that peanut extract treatment of mouse or human plasma induced complement C3a, which could contribute to anaphylaxis (Khodoun *et al.*, 2009). In addition, peanut-reactive T cells have been isolated from the blood of peanut-allergic individuals, suggesting that the hypersensitivity to peanuts also involves a Type IV reaction (de Jong *et al.*, 1996; DeLong *et al.*, 2011).

Exposure to GMOs is becoming more widespread as biotechnological advances in food production are used, for example, to confer insect resistance or provide desired nutrients. Allergenic determinants in GMOs result from the expression of novel proteins that might be recognized as nonself by the immune system. There are several considerations in determining potential hypersensitivity to a GMO. Bioinformatic tools are being developed in order to establish whether the introduced protein is allergenic and/or whether its amino acid sequence is similar enough to known allergens to be considered potentially allergenic (Goodman and Tetteh, 2011; Ladics *et al.*, 2011). In addition, the appropriate test must be selected (eg, radioallergosorbent tests and Ig levels) in order to avoid false positives or false negatives. Finally,

ideally, hypersensitivity to GMOs will be tested on subjects prior to release, but it is also important to survey reactions in the general public following widespread availability (reviewed by Germolec *et al.*, 2003).

Formaldehyde Formaldehyde is used as a preservative, sterilant, and fumigant. Additional exposures come from the textile industry, where it is used to improve wrinkle resistance, and in the furniture, auto upholstery, and resins industries. This low molecular weight compound is extremely soluble in water and forms haptens with human proteins easily (Maibach, 1983). Human predictive testing with 1% to 10% formalin (formalin is 37% formaldehyde) for induction and 1% formalin for challenge showed sensitization rates of 4.5% to 7.8% (Marzulli and Maibach, 1987), and Basketter *et al.* examined 10 aldehydes of varying degrees of allergenicity in humans using the LLNA. The results confirmed that formaldehyde was the strongest allergen and is a contact sensitizer (Basketter *et al.*, 2001).

Occupational exposure to formaldehyde has been associated with the occurrence of asthma (Thompson and Grafstrom, 2008) and increased formaldehyde exposure has now also been associated with increased incidence of childhood asthma (McGwin *et al.*, 2010). Formaldehyde can enhance the respiratory allergic response to other stimuli. For example, Sadakane and coworkers (2002) showed that formaldehyde exposure (0.5% mist once a week for four weeks) in ICR mice enhanced the eosinophilic airway inflammation following the intratracheal instillation with a dust mite allergen. Fujimaki and colleagues (2004) exposed C3H/He mice to formaldehyde at 0, 80, 400, or 2000 ppb formaldehyde for 12 weeks. When mice were immunized with ovalbumin and then exposed to formaldehyde, the total number of BALF cells, macrophages, and eosinophils were significantly increased at the highest concentration. Exposure to 400 ppb formaldehyde induced significant decreases in antiovalbumin IgG1 and IgG3 antibodies, but there was no effect on antiovalbumin IgE antibody. In contrast, in response to a two-week formaldehyde exposure in the absence of another stimulation, total IgE was increased in the serum of C57BL/6 mice (Jung *et al.*, 2007). Lung and liver IL-1 β , IL-4, and IL-5 were also increased, and histopathology showed eosinophil infiltration, and inflammatory cell influx (Jung *et al.*, 2007). It has been postulated that part of the mechanism for formaldehyde-increased pulmonary inflammation involves disruption of airway thiol levels, which could affect levels of reactive oxygen and nitrogen species (Staab *et al.*, 2008; Thompson and Grafstrom, 2008).

Autoimmunity

There are numerous reports of xenobiotics that have been associated with autoimmunity; however, firm evidence for their involvement is difficult to obtain. Presently, there are very few instances of human autoimmune diseases for which an environmental trigger has been definitely identified (Rose, 2005). These relationships may be causative through direct mechanisms, or they may be indirect, acting as an adjuvant. In the area of xenobiotic-induced autoimmunity, exact mechanisms of action are not always known. Chemical exposure may also serve to exacerbate a preexisting autoimmune state (Coleman and Sim, 1994; Kilburn and Warshaw, 1994). Table 12-12 lists chemicals known to be associated with autoimmunity and identifies the proposed self-antigenic determinant for each chemical except for silica, which most likely acts as an adjuvant. Table 12-13 shows chemicals that have been implicated in autoimmune reactions, but in these cases the mechanism of autoimmunity has not been as clearly defined or confirmed. The list includes both

Table 12-12

Chemical Agents Known to be Associated with Autoimmunity

PROPOSED ANTIGENIC CHEMICAL	CLINICAL MANIFESTATIONS	DETERMINANT	REFERENCE
Drugs			
Methyl dopa	Hemolytic anemia	Rhesus antigens	Murphy and Kelton (1991)
Hydralazine	SLE-like syndrome	Myeloperoxidase	Cambridge <i>et al.</i> (1994)
Isoniazid	SLE-like syndrome	Myeloperoxidase	Jiang <i>et al.</i> (1994)
Procainamide	SLE-like syndrome	DNA	Totoritis <i>et al.</i> (1988)
Halothane	Autoimmune hepatitis	Liver microsomal proteins	Kenna <i>et al.</i> (1987)
Nondrug chemicals			
Vinyl chloride	Scleroderma-like syndrome	Abnormal protein synthesized in liver	Ward <i>et al.</i> (1976)
Mercury	Glomerular neuropathy	Glomerular basement membrane protein	Pelletier <i>et al.</i> (1994)
Silica	Scleroderma	Most likely acts as an adjuvant	Pernis and Paronetto (1962)

drug and nondrug chemicals. The heterogeneity of these structures and biological activities illustrate the breadth of potential for the induction of chemically mediated autoimmune disease. A number of recent papers have reviewed some specific examples of xenobiotics associated with autoimmune disease (Pollard *et al.*, 2010), including drugs/immunotherapeutics (D'Cruz, 2000; Pichler, 2003; Vial *et al.*, 2002), vaccines (Descotes *et al.*, 2002; Vial and Descotes, 2004), environmental chemicals (D'Cruz, 2000; Hess, 2002), and pesticides (Holsapple, 2002a). A brief discussion of selected drug and nondrug chemicals is provided.

Therapeutic Agents

Methyldopa Methyldopa is a centrally acting sympatholytic drug that has been widely used for the treatment of essential hypertension; but with the advent of newer antihypertensive drugs, the use of methyldopa has declined. Platelets and erythrocytes are targeted by the immune system in individuals treated with this drug (Garratty, 2010). In the case of thrombocytopenia, antibodies are detected against platelets, which are indicative of immune recognition of a self- or altered self-antigen. Hemolytic anemia occurs in at least 1% of individuals treated with methyldopa, and

up to 30% of these individuals develop antibodies to erythrocytes as manifest in a positive Coombs test. Interestingly, the antibodies are not directed against the chemical or a chemical membrane conjugate.

Hydralazine, Isoniazid, and Procainamide Hydralazine is a direct-acting vasodilator drug used in the treatment of hypertension. Isoniazid is an antimicrobial drug used in the treatment of tuberculosis. Procainamide is a drug that selectively blocks sodium channels in myocardial membranes, making it useful in the treatment of cardiac arrhythmias. All three drugs produce autoimmunity, which is manifested as a SLE-like syndrome. Indeed, procainamide represents one of the best examples for a clear association between exposure to a xenobiotic and the onset or progression of an autoimmune disease. The association between procainamide and the SLE-like condition is based on the finding that the disease remits when the drug is discontinued and recurs when the drug is re-administered. Antibodies to DNA have been detected in individuals showing this syndrome. Studies with hydralazine and isoniazid indicate that the antigenic determinant is myeloperoxidase. Although the actual mechanism by which these drugs induce autoimmunity requires further elucidation, studies suggest a breakdown of central tolerance to low affinity self-antigens in the thymus and altered peripheral tolerance due to inhibition of DNA methylation (reviewed by Chang and Gershwin, 2010). There is no evidence indicating that the immune system is recognizing the chemical or a chemical conjugate. In addition, these drugs have also been shown to produce hypersensitivity responses not associated with the SLE syndrome.

Halothane Halothane, one of the most widely studied of the drugs inducing autoimmunity, is an inhalation anesthetic that can induce autoimmune hepatitis (Reichle and Conzen, 2003). The incidence of this iatrogenic disease in humans is about 1 in 20,000. The pathogenesis of the hepatitis results from the chemical altering a specific liver protein to such a degree that the immune system recognizes the altered protein and antibodies are produced. Studies using rat microsomes show that halothane has to be oxidized by cytochrome P450 enzymes to trifluoroacetylhalide before it binds to the protein. Investigations indicate that in affected individuals antibodies to specific microsomal proteins are produced.

Vinyl Chloride Vinyl chloride, which is used in the plastics industry as a refrigerant and in the synthesis of organic chemicals, is a known carcinogen and is also associated with a scleroderma-like

Table 12-13

Chemicals Implicated in Autoimmunity

MANIFESTATION	IMPLICATED	
	CHEMICAL	REFERENCE
Scleroderma	Solvents (toluene, xylene)	Walder (1983)
	Tryptophan	Silver <i>et al.</i> (1990)
	Silicones	Fock <i>et al.</i> (1984)
Systemic lupus erythematosus	Phenothiazines	Canoso <i>et al.</i> (1990)
	Penicillamine	Harpey <i>et al.</i> (1971)
	Propylthiouracil	DeSwarte (1985)
	Quinidine	Jiang <i>et al.</i> (1994)
	L-DOPA	DeSwarte (1985)
	Lithium carbonate	Ananth <i>et al.</i> (1989)
	Trichloroethylene	Kilburn and Warsaw (1992)
Silicones	Fock <i>et al.</i> (1984)	

syndrome. The disease affects multisystemic collagenous tissues, manifesting itself as pulmonary fibrosis, skin sclerosis, and/or fibrosis of the liver and spleen. Ward *et al.* reported on 320 exposed workers, showing that 58 (18%) had a scleroderma-like syndrome (Ward *et al.*, 1976). The individuals who showed the disease were in a group genetically similar (ie, HLA-DR5) to patients with classic idiopathic scleroderma. Although the exact mechanism whereby this chemical produces autoimmunity is unclear, it is presumed that vinyl chloride acts as an amino acid and is incorporated into protein. Because this would produce a structurally abnormal protein, which would be antigenic, an immune response would be directed against tissues with the modified protein present.

Other occupational exposures suspected to induce scleroderma-like reactions include solvents, particularly organic solvents; but the evidence is still limited. For example, several epidemiological studies found an increased relative risk for scleroderma-like reactions following exposure to solvents when compared to the general population. However, the association was weak and not reproduced in other studies, and these studies frequently assessed exposure to solvents in general without providing details on specific solvents (Garabrant and Dumas, 2000; Garabrant *et al.*, 2003).

Mercury This widely used metal is known to have several target systems, including the CNS and renal system. Mercury also has two different actions with respect to the immune system. The first action is direct injury, described previously in the subsection “Metals” under “Immunomodulation by Xenobiotics.” The second action is mercury-induced autoimmune disease that is manifested as glomerular nephropathy. Antibodies produced to laminin are believed to be responsible for damage to the basement membrane of the kidney. Mice and rats exposed to mercury also show antinuclear antibodies. The role of these antibodies in the autoimmune disease is not clear; however, they represent a known biomarker of autoimmunity. Studies in the brown Norway rat point to a mercury-induced autoreactive CD4⁺ cell as being responsible for the polyclonal antibody response. Mercury chloride induces an increase in the expression of MHCII molecules on B lymphocytes as well as shifting the T helper cell population along the Th2 line. It is the Th2 cell that promotes antibody production. The imbalance between Th1 and Th2 cells is believed to be caused by the depletion of cysteine and the reduced form of glutathione in Th1 cells. Reduced glutathione is known to be important in the synthesis of and responsiveness to IL-2 in T cells. Thus, Th1 cells that synthesize and respond to IL-2 would be at a greater risk than Th2 cells.

Mercury-induced autoimmunity has a strong genetic component. This has been extensively studied in the rat and mouse. For example, some strains of rats, such as the Lewis rat, are completely resistant, while others, such as the brown Norway, are exquisitely sensitive. Susceptibility appears to be linked to 3 or 4 genes, one of which is the MHC. A number of reviews addressing the role of mercury in autoimmunity have been prepared (Bigazzi, 1999; Pelletier *et al.*, 1994; Schiraldi and Monestier, 2009).

Silica Crystalline silica (silicon dioxide) is a primary source of elemental silicon and is used commercially in large quantities as a constituent of building materials, ceramics, concretes, and glasses. Experimental animals as well as humans exposed to silica may have perturbations in the immune system. Depending on the length of exposure, dose, and route of administration of silica, it may kill macrophages or may act as an immunostimulant. Silica has been shown to be associated with an increase in scleroderma in silica-exposed workers (Kilburn and Warshaw, 1994). This effect

is believed to be mediated via an adjuvant mechanism. Adjuvancy as a mechanism of causing autoimmunity has been implicated with a number of other chemicals, including paraffin and silicones. Inherent in adjuvancy as a mechanism of producing autoimmunity is that the population affected by these chemicals must already be at risk for the autoimmune disease. This is supported by the data indicating a genetic component to many autoimmune diseases.

Brown and colleagues (2004) developed a model in which apoptosis plays a critical role in silica-induced autoimmune diseases. As described by the authors, inhalation of crystalline silica results in concurrent activation and apoptosis of the alveolar macrophage resulting in an environment of inflammation and apoptosis. This environment may provide excess self-antigen that is further ingested by activated macrophages or DCs that are able to migrate to local lymph nodes. Within these local lymph nodes, these APCs, laden with apoptotic material, activate T cells and B cells thereby inducing an autoimmune response.

Hexachlorobenzene As noted above, autoimmunity induced by pesticides has been previously reviewed (Holsapple, 2002a). There is little doubt that the pesticide most extensively studied in the context of autoimmunity is hexachlorobenzene. Hexachlorobenzene is a low molecular weight compound that was used in the past as a fungicide for seed grains. Even though its use as a pesticide was prohibited in most countries in the 1970s, it is still generated as a by-product of several industrial processes and trace amounts of hexachlorobenzene are present as contaminants in some chlorine-containing pesticides. Although emissions of hexachlorobenzene have decreased dramatically compared to the 1970s, residues can still be found throughout the environment due to its stability and persistence.

One of the drivers for including hexachlorobenzene in this brief presentation of xenobiotics associated with autoimmune disease is based on an accidental poisoning incident that occurred in Turkey in 1955 to 1959. Approximately, 3000 to 5000 people ingested seed grain contaminated with hexachlorobenzene. Patients developed a disease characterized by hepatic porphyria, called *porphyria turcica*, which was manifested as bullous skin lesions, mainly in sun-exposed skin that ultimately healed with severe scars. The skin lesions have been attributed to the phototoxicity associated with the elevated levels of porphyrins. In addition to the dermatological changes, other clinical manifestations included neurological symptoms, hepatomegaly, enlarged thyroid, splenomegaly, hyperpigmentation, hirsutism, enlarged lymph nodes, and painful arthritis of the hands. For many of the clinical symptoms exhibited by the victims, an immune etiology was considered.

Indeed, the autoimmunogenic potential of hexachlorobenzene has been characterized in a number of laboratory studies, which have been reviewed (Ezendam *et al.*, 2004; Michielsen *et al.*, 1999). The former review emphasized a striking difference in the profile of activity in rats, where the predominant effect was immune enhancement, and in mice, where the predominant effect was immune suppression (Michielsen *et al.*, 1999). Only the former results will be discussed further in this section. Exposure to a variety of strains of rats produced increases in the following types of parameters: peripheral blood counts, serum IgM and IgG levels, autoantibodies, spleen and lymph node weights, marginal zones and follicles of spleens, and primary and secondary antibody responses to tetanus toxoid. Interestingly, exposure to hexachlorobenzene caused opposite effects on two induced autoimmune models in Lewis rats, causing an increase in the severity of experimental allergic encephalomyelitis, and a decrease in the severity of adjuvant arthritis (Michielsen *et al.*, 1999). These findings suggest that comparative

studies using different genetically autoimmune-prone models may be needed to investigate the role of xenobiotics in the onset and progression of autoimmunity.

Concerning a possible mechanism of action, Ezendam *et al.* (2005), proposed that after exposure to hexachlorobenzene, its deposition can directly induce cell damage or elicit damage by interfering with the integrity of cell membranes due to its lipophilic nature. Ultimately, hexachlorobenzene exposure triggers proinflammatory mediators, such as TNF- α , IL-1, IL-6, ROS, and chemokines. These proinflammatory mediators serve as adjuvant signals that induce a systemic inflammatory response with influxes of neutrophils and macrophages into various nonimmune and immune organs. Subsequently, this leads to polyclonal activation of T and B cells, eosinophilia, and eventually to visible clinical effects.

NEW FRONTIERS AND CHALLENGES IN IMMUNOTOXICOLOGY

As noted throughout this chapter, the immune system has unquestionably been identified as a potential target organ for drugs and chemicals. With the demonstration that (1) chemicals can perturb the immune system of animals; (2) perturbation of immune function is correlated with an increased risk of infectious disease; and (3) perturbations in immune function can occur in the absence of any clinically observable effect, attention has focused, and will continue to focus, on the risk to the human population following exposure to chemicals that can alter immune function in animals. In fact, the characterization of the risk associated with xenobiotic-induced immunotoxicity arguably represents one of the key challenges for this discipline in the immediate future.

Risk can be defined as the probability that an adverse event/effect will manifest itself. Risk must also incorporate the hazard, including dose–response relationships, and exposure. Exposure is a function of the amount of chemical involved and the time of its interaction with people and/or the environment. As such, assessment of risk is often an assessment of the probability for exposure. However, most papers in the immunotoxicology literature that are identified as “risk assessment” papers have focused on just one of the above components, most often, hazard identification. Thus, risk assessment in immunotoxicology remains a “New Frontier.”

The science of immunotoxicology continues to evolve, and any overview, including this chapter, must consider the discipline as a “snapshot” in time. Just during the period of time since this chapter was last published, immunotoxicology has experienced significant advancement. This, in part, has been driven by the tremendous growth in knowledge within immunology and cell biology coupled with an explosion in methodological and technological capabilities. New tests reflecting a variety of potential impacts of immunotoxicity have emerged, and traditional tests have been improved. In light of the aforementioned, there are several specific areas within the subdiscipline of immunotoxicology that are currently on the forefront, but will likely see significant advancements and changes. The first, as emphasized earlier in this chapter, will be the continued evolution and application of human primary leukocytes in mechanistic studies of immunotoxicology. In spite of the similarities between the human immune system and that of other animal species, there is an increasing appreciation that often subtle but potentially important differences exist. Advancements in technology, especially flow cytometry have already and will continue to greatly facilitate the application of human primary leukocytes in studies of immunotoxicology. A second area which will see significant changes will be the application

of human-derived cell lines, and validation of assays using these cell lines for the purpose of evaluating and screening potential immunotoxicants. A significant driver for broader employment of cell lines in immunotoxicity testing are cost, ethical considerations to reduce the use of animals in toxicity testing, and a fundamental belief that toxicants which alter one or more of the major signaling pathways regulating cell function can be identified in this manner. A recent report by a National Academy of Sciences committee on “Toxicology in the 21st Century” as well as recent initiatives with US Federal agencies such as ToxCast have brought the strategy of using cell line for hazard identification to the forefront. It is highly likely that a significant shift toward the employment of cell lines in immunotoxicology from current strategies utilizing *in vivo* animal models will require the establishment of a panel of well-characterized cell lines and probably the development of new cell lines in order to make up such a cell line panel. The third area of emphasis in immunotoxicology, as well in other areas of toxicology, will be the application of computational biology to better understand and describe the underlying molecular mechanisms by which an immunotoxicant alters immune function. The application of computational biology has tremendous potential in estimating the potential risk from exposure to immunotoxicants as well as predicting the risk associated with exposure to multiple immunotoxicants simultaneously. The last area on the forefront of immunotoxicology, and in all biomedical disciplines, is increased use of transcriptome analysis. This change will be primarily driven by major advancements and applications of next generation sequencing which will likely make microarrays obsolete due to the significantly greater sensitivity of this technology, decreased cost, and open platform (ie, capable of quantifying the entire transcriptome and not restricted to the DNA tiled on a chip). Moreover, the applications of next generation sequencing beyond studies of the transcriptome are considerable and span uses such as identification of SNPs associated with sensitive subpopulations, and applications in personalized medicine to identification and analysis of DNA methylation for studies of epigenetics.

In spite of these advances, significant challenges remain to be addressed within the discipline of immunotoxicology and include: (1) how to interpret the significance of minor or moderate immunotoxic effects in animal models in relation to human risk assessment; (2) how to better integrate a consideration of exposure, especially to multiple agents simultaneously, into immunotoxicological risk assessment; (3) how to design better human studies to assess the impact on the immune system in the context of risk assessment; (4) how to identify and establish sensitive translational biomarkers of immunotoxicity that can be used to bridge studies conducted in preclinical species to studies in humans; and (5) how to gain a better understanding of the role of genetics in identifying sensitive subpopulations to immune-altering agents. Many of the challenges identified above are not unique to immunotoxicology, but nevertheless are critical, and will need to be addressed through concerted and systematic efforts to improve human immune testing strategies.

Idiosyncratic Liver Injury

Future Directions

INTRODUCTION

The liver is the main organ where exogenous chemicals are metabolized and eventually excreted. As a consequence, liver cells are exposed to significant concentrations of these chemicals, which can result in liver dysfunction, cell injury, and even organ failure. If an industrial chemical, for example carbon tetrachloride, bromobenzene, or vinyl chloride, is identified as a hepatotoxicant, the use of the chemical may be restricted, the exposure may be minimized by mandating protective clothing and respirators, and attempts are made to replace it with a safer alternative. In the pharmaceutical industry, adverse effects on the liver are one of the most frequently cited reasons for discontinuing the development of drug candidates. In addition, hepatotoxicity recognized during the postmarketing phase is one of the main causes for withdrawing drugs from the market (Temple and Himmel, 2002). Troglitazone (Rezulin®), a new antidiabetic drug, was removed from the market after close to 100 of the 1.9 million patients treated with the drug suffered from liver failure (Chojkier, 2005). Thus, predictable and idiosyncratic hepatotoxicities severely restrict drug discovery efforts and drug development (Lee and Senior, 2005). Furthermore, the increasing popularity of herbal medicines, which are generally plant extracts, enhances the incidence of drug-induced liver injury and liver failure (Stickel *et al.*, 2011). Since these medicines are mixtures of sometimes hundreds of compounds, it remains a difficult task to identify the causative chemical and the mechanism of injury (Lee and Senior, 2005). Basic science and clinical aspects of drug- and chemical-induced liver injury were discussed in detail in several monographs and reviews (Zimmerman, 1999; Jaeschke *et al.*, 2002, 2012a, b; Kaplowitz and DeLeve, 2002; Boyer *et al.*, 2006b; Grattagliano *et al.*, 2009; Roth and Ganey, 2010; Jones *et al.*, 2010).

Given the unprecedented speed of drug discovery and the increasing demand and use of “natural products” as food supplements and medicine, the early identification of hepatotoxicants remains a formidable challenge for the future. The liver, with its multiple cell types and numerous functions, can respond in many different ways

to acute and chronic insults. To recognize potential liver cell dysfunction and injury, it is necessary to have a general knowledge of basic liver functions, the structural organization of the liver, the processes involved in the excretory functions of the liver, and mechanisms of cell and organ injury. Each of these aspects can contribute to mechanisms of drug- and chemical-induced hepatotoxicities.

LIVER PHYSIOLOGY

Hepatic Functions

The liver's strategic location between the intestinal tract and the rest of the body facilitates the performance of its enormous task of maintaining metabolic homeostasis of the body (Table 13-1). Venous blood from the stomach and intestine flows into the portal vein and then through the liver before entering the systemic circulation. Thus, the liver is the first organ to encounter ingested nutrients, vitamins, metals, drugs, and environmental toxicants as well as waste products of bacteria that enter portal blood. Efficient scavenging or uptake processes extract these absorbed materials from the blood for catabolism, storage, and/or excretion into bile.

All the major functions of the liver can be detrimentally altered by acute or chronic exposure to toxicants (Table 13-1). When toxicants inhibit or otherwise impede hepatic transport and synthetic processes, dysfunction can occur without appreciable cell damage. Loss of function also occurs when toxicants kill an appreciable number of cells and when chronic insult leads to replacement of cell mass by nonfunctional scar tissue. Alcohol abuse is the major cause of liver disease in most western countries (Crawford, 1999); thus ethanol provides a highly relevant example of a toxicant with multiple functional consequences (Gao and Bataller, 2011). Early stages of ethanol abuse are characterized by lipid accumulation (fatty liver) due to diminished use of lipids as fuels and impaired ability to synthesize the lipoproteins that transport lipids out of the liver. As alcohol-induced liver disease progresses, appreciable cell death occurs, the functioning mass of the

Table 13-1

Major Functions of Liver and Consequences of Impaired Hepatic Functions

TYPE OF FUNCTION	EXAMPLES	CONSEQUENCES OF IMPAIRED FUNCTIONS
Nutrient homeostasis	Glucose storage and synthesis Cholesterol uptake	Hypoglycemia, confusion Hypercholesterolemia
Filtration of particulates	Products of intestinal bacteria (eg, endotoxin)	Endotoxemia
Protein synthesis	Clotting factors Albumin Transport proteins (eg, very low density lipoproteins)	Excess bleeding Hypoalbuminemia, ascites Fatty liver
Bioactivation and detoxification	Bilirubin and ammonia Steroid hormones Xenobiotics	Jaundice, hyperammonemia-related coma Loss of secondary male sex characteristics Diminished drug metabolism Inadequate detoxification
Formation of bile and biliary secretion	Bile acid-dependent uptake of dietary lipids and vitamins Bilirubin and cholesterol Metals (eg, Cu and Mn) Xenobiotics	Fatty diarrhea, malnutrition, Vitamin E deficiency Jaundice, gallstones, hypercholesterolemia Mn-induced neurotoxicity Delayed drug clearance

liver is replaced by scar tissue, and hepatic capacity for biotransformation of certain drugs progressively declines. People with hepatic cirrhosis due to chronic alcohol abuse frequently become deficient at detoxifying both the ammonia formed by catabolism of amino acids and the bilirubin derived from breakdown of hemoglobin. Uncontrollable hemorrhage due to inadequate synthesis of clotting factors is a common fatal complication of alcoholic cirrhosis. A consequence of liver injury that merits emphasis is that loss of liver functions can lead to aberrations in other organ systems and to death (Gao and Bataller, 2011).

Structural Organization

Two concepts exist for organization of the liver into operational units, namely, the lobule and the acinus (McCuskey, 2006b). Classically, the liver was divided into hexagonal lobules oriented around terminal hepatic venules (also known as central veins). At the corners of the lobule are the portal triads (or portal tracts), containing a branch of the portal vein, a hepatic arteriole, and a bile duct (Fig. 13-1). Blood entering the portal tract via the portal vein and hepatic artery is mixed in the penetrating vessels, enters the sinusoids, and percolates along the cords of parenchymal cells (hepatocytes), eventually flows into terminal hepatic venules, and exits the liver via the hepatic vein. The lobule is divided into three regions known as centrilobular, midzonal, and periportal. The acinus is the preferred concept for a functional hepatic unit. The terminal branches of the portal vein and hepatic artery, which extend out from the portal tracts, form the base of the acinus. The acinus has three zones: zone 1 is closest to the entry of blood, zone 3 abuts the terminal hepatic vein, and zone 2 is intermediate. Despite the utility of the acinar concept, lobular terminology is still used to describe regions of pathological lesions of hepatic parenchyma. Fortunately, the three zones of the acinus roughly coincide with the three regions of the lobule (Fig. 13-1).

Acinar zonation is of considerable functional consequence regarding gradients of components both in blood and in hepatocytes (Jungermann and Kietzmann, 2000). Blood entering the acinus consists of oxygen-depleted blood from the portal vein

(60%–70% of hepatic blood flow) plus oxygenated blood from the hepatic artery (30%–40%). Enroute to the terminal hepatic venule, oxygen rapidly leaves the blood to meet the high metabolic demands of the parenchymal cells. Approximate oxygen concentrations in zone 1 are 9% to 13%, compared with only 4% to 5% in zone 3 (Kietzmann and Jungermann, 1997). Therefore, hepatocytes in zone 3 are exposed to substantially lower concentrations of oxygen than hepatocytes in zone 1. In comparison to other tissues, zone 3 is hypoxic. Another well-documented acinar gradient is that of bile salts (Groothuis *et al.*, 1982). Physiological concentrations

Figure 13-1. Schematic of liver operational units, the classic lobule and the acinus. The lobule is centered around the terminal hepatic vein (central vein), where the blood drains out of the lobule. The acinus has as its base the penetrating vessels, where blood supplied by the portal vein and hepatic artery flows down the acinus past the cords of hepatocytes. Zones 1, 2, and 3 of the acinus represent metabolic regions that are increasingly distant from the blood supply.

Figure 13-2. Schematic of liver sinusoidal cells. Note that the Kupffer cell resides within the sinusoidal lumen. The stellate cell is located in the space of Disse between the thin, fenestrated endothelial cells, and the cord of hepatocytes.

of bile salts are efficiently extracted by zone 1 hepatocytes with little bile acids left in the blood that flows past zone 3 hepatocytes. There is difference in bile acid transporter expression between different zones (Baier *et al.*, 2006).

Heterogeneities in protein levels of hepatocytes along the acinus generate gradients of metabolic functions. Hepatocytes in the mitochondria-rich zone 1 are predominant in fatty acid oxidation, gluconeogenesis, and ammonia detoxification to urea. Gradients of enzymes involved in the bioactivation and detoxification of xenobiotics have been observed along the acinus by immunohistochemistry (Jungermann and Katz, 1989; Gebhardt *et al.*, 1994). Notable gradients for hepatotoxins are the higher levels of glutathione (GSH) in zone 1 and the greater amounts of cytochrome P450 proteins in zone 3, particularly the CYP2E1 isozyme inducible by ethanol (Tsutsumi *et al.*, 1989; Niemelä *et al.*, 2000).

Hepatic sinusoids are the channels between cords of hepatocytes where blood percolates on its way to the terminal hepatic vein. Sinusoids are larger and more irregular than normal capillaries. The three major types of cells in the sinusoids are endothelial cells, Kupffer cells, and stellate cells (Fig. 13-2) (McCuskey, 2006b). In addition, the liver contains a substantial number of lymphocytes, especially natural killer (NK) and NKT cells (Gao *et al.*, 2009). Sinusoids are lined by thin, discontinuous endothelial cells with numerous fenestrae (or pores) that allow molecules smaller than 250 kDa to cross the interstitial space (known as the space of Disse) between the endothelium and hepatocytes. Sinusoidal endothelial cells are separated from the hepatocytes by a basement membrane-like matrix, which is not as electron-dense as a regular basement membrane (Friedman, 2000). However, this subendothelial extracellular matrix is important for the normal function of all resident liver cells (Friedman, 2000). The numerous fenestrae and the lack of basement membrane facilitate exchanges of fluids and molecules, such as albumin, between the sinusoid and hepatocytes, but hinder movement of particles larger than chylomicron remnants. Endothelial cells are important in the scavenging of lipoproteins via the apo E receptor and of denatured proteins and advanced glycation endproducts by the scavenger receptor (Enomoto *et al.*, 2004; Elvevold *et al.*, 2008). Hepatic endothelial cells also secrete cytokines, prostanoids, nitric oxide, and endothelins and express intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1) on the cell surface (Jaeschke, 1997).

Kupffer cells are the resident macrophages of the liver and constitute approximately 80% of the fixed macrophages in the body (McCuskey, 2006b). Kupffer cells are situated within the lumen of the sinusoid. The primary function of Kupffer cells is to ingest and degrade particulate matter. Also, Kupffer cells are a major source

of cytokines and eicosanoids and can act as antigen-presenting cells (APCs; Laskin, 2009). Hepatic stellate cells (HSCs; also known as Ito cells or by the more descriptive terms of *fat-storing cells*) are located between endothelial cells and hepatocytes (Friedman, 2008). Stellate cells are the major sites for vitamin A storage in the body (Friedman, 2008). Upon activation, these cells can synthesize and excrete collagen and other extracellular matrix proteins and express smooth muscle actin (Friedman, 2000; Lee and Friedman, 2011).

Bile Formation

Bile is a yellow fluid containing bile acids, GSH, phospholipids, cholesterol, bilirubin and other organic anions, proteins, metals, ions, and xenobiotics (Klaassen and Watkins, 1984). Formation of this fluid is a specialized function of the liver. Adequate bile formation is essential for uptake of lipid nutrients from the small intestine (Table 13-1), for protection of the small intestine from oxidative insults (Aw, 1994), and for excretion of endogenous and xenobiotic compounds. Hepatocytes begin the process of bile formation by transporting bile acids, GSH, and other osmotically active compounds including xenobiotics and their metabolites into the canalicular lumen. These molecules are the major driving force for the passive movement of water and electrolytes across the tight junctions and the hepatocyte epithelium. The canalicular lumen is a space formed by specialized regions of the plasma membrane between adjacent hepatocytes (Fig. 13-2). The canaliculi are separated from the intercellular space between hepatocytes by tight junctions, which form a barrier permeable only to water, electrolytes, and to some degree to small organic cations. Under physiological conditions, tight junctions are impermeable to organic anions allowing the high concentrations of bile acids, GSH, bilirubin diglucuronide, and other organic anions in bile. The structure of the biliary tract is analogous to the roots and trunk of a tree, where the tips of the roots equate to the canalicular lumens. Canaliculi form channels between hepatocytes that connect to a series of larger and larger channels or ducts within the liver. The large extrahepatic bile ducts merge into the common bile duct. Bile can be stored and concentrated in the gallbladder before its release into the duodenum. However, the gallbladder is not essential to life and is absent in several species, including the horse, whale, and rat.

With the identification of specific transporters, substantial progress has been made in the understanding of the molecular mechanisms of bile formation (reviewed by Jansen and Groen, 2006; Pauli-Magnus and Meier, 2006). On the basal (sinusoidal) side of the hepatocytes, there are sodium-dependent and sodium-independent uptake systems. Most conjugated bile acids (taurine and glycine conjugates) and some of the unconjugated bile acids are transported into hepatocytes by sodium/taurocholate cotransporting polypeptide (NTCP) (Fig. 13-3) (Trauner and Boyer, 2003; Hagenbuch and Dawson, 2004; Stieger *et al.*, 2007). Sodium-independent uptake of conjugated and unconjugated bile acids is performed by members of the organic anion transporting polypeptides (OATPs) (Hagenbuch and Meier, 2004; Csanky *et al.*, 2011). OATP1B1 and OATP1B3 are predominantly expressed in liver and are capable of transporting conjugated and unconjugated bile acids and steroids, bromosulfophthalein, and many other organic anions. Furthermore, the OATPs are transporting numerous drugs and also some hepatotoxins, for example, phalloidin, microcystin, and amanitin (Hagenbuch and Gui, 2008; Roth *et al.*, 2011). In addition to the uptake systems, there are ATP-dependent efflux pumps located on the basolateral membrane of hepatocytes. These carriers are members of the multidrug resistance-associated proteins (MRPs;

Figure 13-3. Transport proteins in human hepatocytes and cholangiocytes. Efflux transporters (blue symbols): BSEP, bile salt export pump; MDR, multidrug resistance protein; MRP, multidrug resistance-associated protein; ABCG5/8; BCRP, breast cancer resistance protein; Ost α /Ost β . Uptake transporters (red symbols): ASBT, apical sodium-dependent bile salt transporter; NTCP, sodium taurocholate cotransporting polypeptide; OATP, organic anion-transporting polypeptide; OCT, organic cation transporter; OAT, organic anion transporter. Transporters localized to the sinusoidal membrane extract solutes from the blood. Exporters localized to the canalicular membrane move solutes into the lumen of the canaliculus. Exporters of particular relevance to canalicular secretion of toxic chemicals and their metabolites are the canalicular multiple organic anion transporter (MOAT) system and the family of multiple-drug resistant (MDR) P-glycoproteins. Note: MDR3(ABCB4) flips phosphatidylcholine from the inner to the outer leaflet of the canalicular membrane. Phosphatidylcholine can then be extracted by bile salts. ATP8B1 together with the accessory protein CDC50A flips phosphatidylserine from the outer to the inner membrane to maintain the lipid asymmetry of the canalicular membrane and to protect against bile acids (Groen *et al.*, 2011). (Adapted from Pauli-Magnus and Meier (2006). Reprinted with permission of John Wiley & Sons, Inc.)

ABCC), which are multispecific transporters for many different anions (Homolya *et al.*, 2003) (Fig. 13-3).

All unconjugated bile acids in hepatocytes are conjugated before being transported by the bile salt export pump (BSEP) across the canalicular membrane. Bile acid excretion is a major driving force of bile formation (bile salt-dependent bile flow). Other constituents of bile are transported by members of the multidrug resistance (MDR) P-glycoprotein family such as MDR3 (ABCC2), which transports phospholipids, and the heterodimeric transporters ABCG5/ABCG8, which transport cholesterol and plant sterols into bile (Pauli-Magnus and Meier, 2006). In addition, MRP2 (a member of the multidrug resistance-associated proteins) transports GSH, which is the main compound responsible for the bile salt-independent bile flow, as well as sulfated and glucuronidated bile acids, glutathione disulfide and glutathione conjugates, bilirubin diglucuronide, and many other conjugated drugs and chemicals (Gerk and Vore, 2002; Borst *et al.*, 2000). Other transport systems of the canalicular membrane include the breast cancer resistance protein (BCRP; ABCG2), which can contribute to the biliary excretion of bile acids and xenobiotics.

Metals are excreted into bile by a series of processes that include (1) uptake across the sinusoidal membrane by facilitated diffusion or receptor-mediated endocytosis; (2) storage in binding proteins or lysosomes; and (3) canalicular secretion via lysosomes, a GSH-coupled event, or use of specific canalicular membrane transporter, for example MRP2 (Ballatori, 2002). Biliary excretion is important in the homeostasis of multiple metals, notably copper, manganese, cadmium, selenium, gold, silver, and arsenic (Klaassen, 1976; Gregus and Klaassen, 1986). Species differences are known for biliary excretion of several toxic metals; for example, dogs excrete arsenic into bile much more slowly than rats. Inability to export copper into bile is a central problem in Wilson's disease, a rare autosomal recessive inherited disorder characterized by a defect or the absence of a copper transporting P-type ATPase (ATP7B). This carrier is located in the trans-Golgi network and transports copper into the secretory pathway for binding to ceruloplasmin and then excretion into bile (Loudianos and Gitlin, 2000). Because biliary excretion is the only way to eliminate copper, a defect in ATP7B results in excessive copper accumulation in hepatocytes, which causes chronic hepatitis and cirrhosis (Loudianos and Gitlin, 2000).

Canalicular lumen bile is propelled forward into larger channels by dynamic, ATP-dependent contractions of the pericanalicular cytoskeleton (Watanabe *et al.*, 1991). Bile ducts, once regarded as passive conduits, modify bile by absorption and secretion of solutes (Lira *et al.*, 1992). Bile acids are taken up into biliary epithelial cells (cholangiocytes) by OATP1A2 (sodium-independent uptake) and by the sodium-dependent bile acid transporter ASBT (Hagenbuch and Dawson, 2004; Hagenbuch and Meier, 2004). These bile acids are then excreted on the basolateral side mainly by MRP3 and heterodimeric organic solute transporter (OST α /OST β) (Ballatori *et al.*, 2005). The bile acids excreted from cholangiocytes return to the portal circulation via the peribiliary plexus (cholehepatic shunt pathway). Biliary epithelial cells also express a variety of phase I and phase II enzymes, which may contribute to the biotransformation of chemical toxicants present in bile (Lakehal *et al.*, 1999).

Secretion into biliary ducts is usually but not always a prelude to toxicant clearance by excretion in feces or urine. Exceptions occur when compounds such as arsenic are repeatedly delivered into the intestinal lumen via bile, efficiently absorbed from the intestinal lumen, and then redirected to the liver via portal blood, a process known as *enterohepatic cycling*. A few compounds, such as methyl mercury, are absorbed from the biliary tract; the extensive reabsorption of methyl mercury from the gallbladder is thought to contribute to the long biological half-life and toxicity of this toxicant (Dutczak *et al.*, 1991). Alternatively, secretion into bile of toxicant metabolites can be a critical prelude to the development of injury in extrahepatic tissues. A clinically relevant example of bile as an important delivery route for a proximate toxicant is that of diclofenac, a widely prescribed nonsteroidal anti-inflammatory drug (NSAID) that causes small intestinal ulceration. Experiments with mutant rats lacking a functional MRP2 exporter (Fig. 13-3) have shown that these mutants secrete little of the presumptive proximate toxicant metabolite into bile and are resistant to the intestinal toxicity of diclofenac (Seitz and Boelsterli, 1998).

Toxicant-related impairments of bile formation are more likely to have detrimental consequences in populations with other conditions where biliary secretion is marginal. For example, neonates exhibit delayed development of multiple aspects of bile formation, including synthesis of bile acids and the expression of sinusoidal and canalicular transporters (Arrese *et al.*, 1998). Neonates are more prone to develop jaundice when treated with drugs that compete with bilirubin for biliary clearance. Individuals with genetic deficiency of certain transporters are not only at risk for chronic liver injury and fibrosis, but may also be more susceptible to drugs and hepatotoxicants (Jansen and Sturm, 2003; Jansen and Groen, 2006). Patients with sepsis frequently develop cholestasis, which is

mainly caused by downregulation of multiple canalicular transport systems (Geier *et al.*, 2006). In addition, direct inhibition of BSEP, as was shown for the endothelin receptor antagonist bosentan, can lead to retention of bile acids in the liver and potentially cell injury (Fattinger *et al.*, 2001).

LIVER PATHOPHYSIOLOGY

Mechanisms and Types of Toxicant-Induced Liver Injury

The response of the liver to chemical exposure depends on the intensity of the insults, the cell population affected, and the duration of the chemical exposure (acute vs chronic). Milder stresses may just cause reversible cellular dysfunction, for example, temporary cholestasis after exposure to estrogens, and could cause an adaptive response (conditioning). However, acute poisoning with acetaminophen (APAP) or carbon tetrachloride triggers parenchymal cell necrosis. Exposure to ethanol induces steatosis, which may enhance the susceptibility to subsequent inflammatory insults (Table 13-2). Note that the representative hepatotoxins listed in Table 13-2 include pharmaceuticals (valproic acid, cyclosporin A, diclofenac, APAP, and tamoxifen), recreational drugs (ethanol, ecstasy), a vitamin (vitamin A), metals (Fe, Cu, and Mn), hormones (estrogens, androgens), industrial chemicals (dimethylformamide, methylene dianiline), compounds found in teas (germander) or foods (phalloidin, pyrrolidine alkaloids), and toxins produced by fungi (sporidesmin) and algae (microcystin).

Cell Death Based on morphology, liver cells can die by two different modes, oncotic necrosis (“necrosis”) or apoptosis. Necrosis is characterized by cell swelling, leakage of cellular contents, nuclear disintegration (karyolysis), and an influx of inflammatory cells. Because necrosis is generally the result of an exposure to a toxic chemical or other traumatic conditions, for example, ischemia, large numbers of contiguous hepatocytes and nonparenchymal cells may be affected. Cell contents released during oncotic necrosis include proteins such as a high-mobility group box-1 (HMGB1) and other alarmins, which are a subset of the larger class of damage-associated molecular patterns (DAMPs) (Bianchi, 2007). These molecules are recognized by cells of the innate immune system including Kupffer cells through their toll-like receptors trigger cytokine formation, which orchestrate the inflammatory response after tissue injury. Thus, an ongoing oncotic necrotic process can be identified by the release of liver-specific enzymes such as alanine (ALT) or aspartate (AST) aminotransferase into the plasma and by

Table 13-2

Types of Hepatobiliary Injury

TYPE OF INJURY OR DAMAGE	REPRESENTATIVE TOXINS
Fatty liver	Amiodarone, CCl ₄ , ethanol, fialuridine, tamoxifen, valproic acid
Hepatocyte death	Acetaminophen, allyl alcohol, Cu, dimethylformamide, ethanol
Immune-mediated response	Diclofenac, ethanol, halothane, tienilic acid
Canalicular cholestasis	Chlorpromazine, cyclosporin A, 1,1-dichloroethylene, estrogens, Mn, phalloidin
Bile duct damage	Alpha-naphthylisothiocyanate, amoxicillin, methylenedianiline, sporidesmin
Sinusoidal disorders	Anabolic steroids, cyclophosphamide, microcystin, pyrrolizidine alkaloids
Fibrosis and cirrhosis	CCl ₄ , ethanol, thioacetamide, vitamin A, vinyl chloride
Tumors	Aflatoxin, androgens, arsenic, thorium dioxide, vinyl chloride

Figure 13-4. *Fas* receptor-mediated apoptotic signaling pathways in hepatocytes. AIF, apoptosis-inducing factor; Apaf1, apoptosis protease-activating factor-1; CARD, caspase-activating and -recruiting domain; Casp, caspase; c, cytochrome c; cIAP, cellular inhibitor of apoptosis proteins; DD, death domain; Smac, second mitochondria-derived activator of caspases; DISC, death-inducing signaling complex; EndoG, endonuclease G; FADD, Fas-associated death domain; FAS-L, Fas-ligand; FLIP, FLICE-inhibitory protein. (Adapted from Jaeschke, 2006a.)

histology, where areas of necrosis with loss of nuclei and inflammatory infiltrates are easily detectable in H&E sections. In contrast, apoptosis is characterized by cell shrinkage, chromatin condensation, nuclear fragmentation, formation of apoptotic bodies, and, generally, a lack of inflammation. The characteristic morphological features of apoptosis are caused by the activation of caspases, which trigger the activation of enzymes such as caspase-activated DNase (CAD) responsible for internucleosomal DNA fragmentation (Nagata *et al.*, 2003). In addition, caspases can directly cleave cellular and nuclear structural proteins (Fischer *et al.*, 2003). Apoptosis is always a single cell event with the main purpose of removing cells no longer needed during development or eliminating aging cells during regular tissue turnover. Under these conditions, apoptotic bodies are phagocytosed by Kupffer cells or taken up by neighboring hepatocytes. In the absence of cell contents release, the remnants of apoptotic cells disappear without causing an inflammatory response. Because of effective regeneration, apoptotic cell death during normal tissue turnover or even a moderately elevated rate of apoptosis is of limited pathophysiological relevance in the liver. However, if the rate of apoptosis is substantially increased, the apoptotic process cannot be completed. In this case, cells undergo secondary necrosis with breakdown of membrane potential, cell swelling, and release of cell contents (Ogasawara *et al.*, 1993; Bajt *et al.*, 2000). The fundamental difference between oncotic necrosis and secondary necrosis is the fact that during secondary necrosis many apoptotic cells can still be identified based

on morphology, many apoptotic characteristics such as activation of various caspases are present, and the process can be completely inhibited by potent pancaspase inhibitors (Jaeschke *et al.*, 2004). Oncotic necrosis does not involve relevant caspase activation and is not inhibitable by caspase inhibitors.

In recent years, signaling mechanisms of apoptosis were elucidated in great detail (Fig. 13-4) (reviewed by Jaeschke, 2006a; Malhi *et al.*, 2006; Schulze-Bergkamen *et al.*, 2006). In the extrinsic pathway of apoptosis, ligands (eg, Fas ligand, TNF- α) bind to their respective death receptor (Fas receptor, TNF receptor type I), which triggers the trimerization of the receptor followed by recruitment of various adapter molecules and procaspases to the cytoplasmic tail of the receptor. The assembly of this death-inducing signaling complex (DISC) leads to the activation of initiator caspases (caspase-8 or -10). In hepatocytes, the active initiator caspase cleaves Bid, a member of the Bcl-2 family of proteins, and the truncated Bid (tBid) translocates together with other Bcl-2 family members such as Bax to the mitochondria. These proteins form pores in the outer membrane of the mitochondria and cause the release of intermembrane proteins such as cytochrome *c* and the second mitochondria-derived activator of caspases (Smac). Cytochrome *c*, together with apoptosis protease activating factor-1 (APAF-1), ATP, and procaspase-9, forms the apoptosome causing the activation of caspase-9, which then processes (and activates) downstream effector caspases, for example caspase-3. The effector caspases can propagate the apoptosis signal by activating CAD to initiate nuclear DNA fragmentation

and by cleaving numerous cellular proteins critical to cellular function and the structural integrity of the cell and the nucleus (Fischer *et al.*, 2003; Nagata *et al.*, 2003). In addition to downstream substrates, caspase-3 can also process more procaspase-8 and further amplify the apoptotic signal. Although hepatocytes constitutively express Fas and TNF receptors, the death signal generated with ligation of the receptor is in most cases insufficient to trigger apoptosis. Inhibitor studies and experiments with gene-deficient mice support the hypothesis that only the amplification of the receptor-derived signal through multiple mitochondrial cycles can successfully induce apoptosis in hepatocytes (Yin *et al.*, 1999; Bajt *et al.*, 2000). In addition to the direct propagation of the apoptosis signal by mitochondrial cytochrome *c* release, the simultaneous release of Smac ensures that the cytosolic inhibitors of apoptosis proteins (IAPs) are inactivated and do not interfere with the promotion of apoptosis (Li *et al.*, 2002). Thus, mitochondria are an important part of the extrinsic (receptor-mediated) apoptotic signal transduction pathway in liver cells after most stimuli (type II cells). However, it was recently recognized that under conditions of strong Fas receptor activation (MegaFas ligand), hepatocytes can act as type I cells where downstream caspases are activated without involvement of mitochondria (Schüngel *et al.*, 2009).

In contrast to the extrinsic pathway, the intrinsic or mitochondrial pathway of apoptosis is initiated independent of the TNF receptor family, caspase-8 activation, and formation of the DISC. Despite the upstream differences, the postmitochondrial effects are largely similar to the extrinsic pathway. The intrinsic pathway is generally triggered by a cytotoxic stress or DNA damage, which activates the tumor suppressor p53 (Sheikh and Fornace, 2000). This protein acts as a transcription factor to promote the formation of proapoptotic Bcl-2 family members, for example, Bax. The increased Bax translocation to the mitochondria induces the release of mitochondrial intermembrane proteins including cytochrome *c*, Smac, endonuclease G, and apoptosis-inducing factor (AIF) (Saelens *et al.*, 2004). An intrinsic mechanism of apoptosis has been discussed for cell death in aging livers (Zhang *et al.*, 2002), prolonged treatment with alcohol (Ishii *et al.*, 2003), or toxicity of benzo(*a*)pyrene and APAP in hepatoma cells (Boulares *et al.*, 2002; Ko *et al.*, 2004). For other hepatotoxic chemicals, such as carbon tetrachloride (Cai *et al.*, 2005), galactosamine (Gomez-Lechon *et al.*, 2002), and microcystin (Ding *et al.*, 2000), evidence for mitochondria-dependent apoptosis has been reported in cultured hepatocytes and relevant apoptotic cell death was observed after in vivo exposure to these chemicals (Shi *et al.*, 1998; Hooser, 2000; Gujral *et al.*, 2003b).

The dramatically increased knowledge of the signaling mechanisms of apoptotic cell death in hepatocytes lead to the identification of many biochemical "apoptosis" parameters, most of which turned out to be not as specific for apoptosis as originally thought. Prominent examples of these tests are the DNA ladder on agarose gels and the terminal deoxynucleotidyl transferase-mediated dUTP nick-end labeling (TUNEL) assay, which demonstrate internucleosomal DNA fragmentation and DNA strandbreaks, respectively. Originally thought to specifically identify apoptotic cells, both assays are positive for most mechanisms of necrotic cell death (Grasl-Kraupp *et al.*, 1995; Gujral *et al.*, 2002; Jaeschke and Lemasters, 2003). As a result of the misinterpretation of many of these assays, the contribution of apoptosis to the overall pathophysiology processes and toxicological liver injuries is controversially debated (Jaeschke and Lemasters, 2003; Jaeschke *et al.*, 2004; Malhi *et al.*, 2006; Schulze-Bergkamen *et al.*, 2006). However, the controversy can be avoided if the decision to label the process as apoptosis is based primarily on the morphological features of

the dying cells. Because the characteristic morphology is caused by the caspase-mediated cleavage of structural proteins within the cell, relevant caspase activation, especially of downstream effector caspases such as caspase-3 or -6, is another hallmark of apoptosis. As a result, pancaspase inhibitors can effectively prevent apoptosis-induced liver injury in vivo and in isolated hepatocytes. It should be emphasized that liver cells contain enough procaspases to execute apoptosis if properly stimulated. Thus, changes in caspase gene or protein expression are not evidence for apoptosis, only a relevant increase of enzyme activity. Once the process is identified as apoptosis, additional parameters can be used to further characterize the signaling mechanism. In addition, the use of positive controls, for example, Fas ligand- or TNF-mediated hepatocellular apoptosis, can be helpful in assessing qualitative and quantitative changes of many parameters relative to a proven apoptotic process (Jaeschke *et al.*, 2004). Another critical issue to consider is the model system that is being used. For example, both the antidiabetic drug troglitazone and the analgesic APAP clearly induce apoptosis in hepatoma cell lines (Yamamoto *et al.*, 2001; Boulares *et al.*, 2002). However, there is no evidence for a relevant role of apoptotic cell death in animals or patients for both drugs (Gujral *et al.*, 2002; Chojkier, 2005; Antoine *et al.*, 2012; McGill *et al.*, 2012b). Thus, characterization of cell death after chemical exposure has to be primarily based on morphology and a number of additional biochemical parameters, which need to quantitatively correlate with the number of apoptotic cells. In addition, the relevance of the model system for the human pathophysiology needs to be considered.

The mechanisms of oncotic necrosis are more diverse and depend on the chemical insult to the cell (a detailed example of the mechanism of APAP-induced hepatocellular necrosis is discussed later). However, a general trend is emerging. Independent of the initial insult and signaling pathways, mitochondria are almost always involved in the pathophysiology (Jaeschke *et al.*, 2012a; Pessayre *et al.*, 2012). The opening of the mitochondrial membrane permeability transition (MPT) pore with collapse of the membrane potential and depletion of cellular ATP is a common final step of the mechanism of necrotic cell death (Kim *et al.*, 2003). The loss of ATP inhibits ion pumps of the plasma membrane resulting in the loss of cellular ion homeostasis, which causes the characteristic swelling of oncotic necrosis. A special form of cell death is the more recently described *programmed necrosis (necroptosis)* (Vandenabeele *et al.*, 2010). Necroptosis is generally initiated by death receptors, for example TNF receptor 1, and the formation of complex 1 with various adapter molecules including receptor-interacting protein 1 and 3 (RIP1 and -3). If caspase-8 is activated, it will cleave RIP1 and -3 and apoptosis will be initiated. However, if caspase-8 is inhibited, RIP1 and -3 activate a caspase-independent execution mechanism involving mitochondrial oxidant stress and mitochondrial dysfunction (Vandenabeele *et al.*, 2010). Although some of these signaling mechanisms of necroptosis have been described for various cell lines, the importance for liver cell death, especially in vivo, remains unclear.

Canalicular Cholestasis This form of liver dysfunction is defined physiologically as a decrease in the volume of bile formed or an impaired secretion of specific solutes into bile (Padda *et al.*, 2011). Cholestasis is characterized biochemically by elevated serum levels of compounds normally concentrated in bile, particularly bile salts and bilirubin. When biliary excretion of the yellowish bilirubin pigment is impaired, this pigment accumulates in skin and eyes, producing jaundice, and spills into urine, which becomes bright yellow or dark brown. Because drug-induced jaundice reflects a more generalized liver dysfunction, it is considered

a more serious warning sign in clinical trials than mild elevations of liver enzymes (Zimmerman, 1999). The histological features of cholestasis can be very subtle and difficult to detect without ultrastructural studies. Structural changes include dilation of the bile canaliculus and the presence of bile plugs in bile ducts and canaliculi. Toxicant-induced cholestasis can be transient or chronic; when substantial, it is associated with cell swelling, cell death, and inflammation. Cell injury is generally caused by the accumulation of chemicals in the liver, that is, the cholestasis-causing chemical and, as a consequence, potentially cytotoxic bile acids, bilirubin, and other bile constituents. Many different types of chemicals, including metals, hormones, and drugs, cause cholestasis (Table 13-2) (Zimmerman, 1999).

The molecular mechanisms of cholestasis are related to expression and function of transporter systems in the basolateral and canalicular membranes (reviewed by Pauli-Magnus and Meier, 2006; Padda *et al.*, 2011) (Fig. 13-3). In principle, an increased hepatic uptake, decreased biliary excretion, and increased biliary reabsorption (cholehepatic shunting) of a drug may contribute to its accumulation in the liver. Although no case of drug toxicity has been reported in response to modifications of basolateral uptake, OATPs can contribute to the liver injury potential of toxins. The hepatotoxicity of phalloidin, microcystin, and amanitin is facilitated by the uptake through OATPs (Pauli-Magnus and Meier, 2006; Lu *et al.*, 2008). Furthermore, there is a growing list of drugs including rifampicin, bosentan, and troglitazone, which are known to directly inhibit BSEP (Stieger *et al.*, 2000; Fattinger *et al.*, 2001). However, estrogen and progesterone metabolites inhibit BSEP from the canalicular side after excretion by MRP2 (Stieger *et al.*, 2000). A substantial inhibition of bile salt excretion can lead to accumulation of these compounds in hepatocytes and may directly cause cell injury (Palmeira and Rolo, 2004). However, more recent findings indicate that most of the bile acids accumulating in the liver after obstructive cholestasis are nontoxic (Zhang *et al.*, 2012) and instead of cell death cause proinflammatory gene expression in hepatocytes (Allen *et al.*, 2011). Thus, liver injury after obstructive cholestasis is caused mainly by inflammatory cells (Gujral *et al.*, 2003a). However, the increased bile acid levels can trigger compensatory mechanisms, which limit the injury potential of cholestasis (Zollner *et al.*, 2006; Zhang *et al.*, 2012). Bile acids are substrates for the nuclear receptor farnesoid X receptor (FXR). FXR activation stimulates the small heterodimeric partner 1 (SHP1), which downregulates NTCP and limits bile acid uptake (Denson *et al.*, 2001). In addition, FXR activation causes the increased expression of BSEP and MDR3, which enhances the transport capacity for bile acids and phospholipids, respectively, at the canalicular membrane (Ananthanarayanan *et al.*, 2001; Huang *et al.*, 2003). Furthermore, the FXR-independent upregulation of the basolateral transporters MRP3 and MRP4 reduces intracellular bile acid and drug concentrations (Schuetz *et al.*, 2001; Wagner *et al.*, 2003; Fickert *et al.*, 2006). Recent findings indicate that agonists of the nuclear xenobiotic receptors constitutive androstane receptor (CAR) and pregnane X receptor (PXR) can not only induce MRP3 and -4 expression, but also induce bile acid hydroxylation by Cyp3a11 and Cyp2b10 resulting in improved export and detoxification of bile acids during cholestasis (Wagner *et al.*, 2005). In cholangiocytes, OST α /OST β is upregulated at the basolateral membrane during cholestasis (Boyer *et al.*, 2006a). This response, which is dependent on FXR, mediates the enhanced return of bile acids from bile to the plasma (Boyer *et al.*, 2006a). Thus, the pharmacological modulation of transporter expression may counteract some of the detrimental effects of cholestasis with various etiologies (Zollner *et al.*, 2006).

Bile Duct Damage Another name for damage to the intrahepatic bile ducts is *cholangiodestructive cholestasis* (Cullen and Ruebner, 1991; Zimmerman, 1999). A useful biochemical index of bile duct damage is a sharp elevation in serum activities of enzymes localized to bile ducts, particularly alkaline phosphatase. In addition, serum levels of bile acids and bilirubin are elevated, as observed with canalicular cholestasis. Initial lesions following a single dose of cholangiodestructive chemicals include swollen biliary epithelium, debris of damaged cells within ductal lumens, and inflammatory cell infiltration of portal tracts. Chronic administration of toxicants that cause bile duct destruction can lead to biliary proliferation and fibrosis resembling primary biliary cirrhosis (PBC). A number of drugs have been implicated to cause prolonged cholestasis with features of PBC (Zimmerman, 1999). However, only in rare cases will there be permanent damage or even loss of bile ducts, a condition known as *vanishing bile duct syndrome*. Cases of this persisting problem have been reported in patients receiving antibiotics (Davies *et al.*, 1994), anabolic steroids, contraceptive steroids, or the anticonvulsant carbamazepine (Zimmerman, 1999).

Sinusoidal Damage The sinusoid is, in effect, a specialized capillary with numerous fenestrae for high permeability (Braet and Wisse, 2002). The functional integrity of the sinusoid can be compromised by dilation or blockade of its lumen or by progressive destruction of its endothelial cell wall. Dilation of the sinusoid will occur whenever efflux of hepatic blood is impeded. The rare condition of primary dilation, known as *peliosis hepatis*, has been associated with exposure to anabolic steroids and the drug danazol. Blockade will occur when the fenestrae enlarge to such an extent that red blood cells become caught in them or pass through with entrapment in the interstitial space of Disse. Endothelial cell gaps and injury have been shown after exposure to APAP (Ito *et al.*, 2005), galactosamine/endotoxin (Ito *et al.*, 2006), or an anti-Fas antibody (Ogasawara *et al.*, 1993). These gaps can be caused by direct injury to endothelial cells by APAP (DeLeve *et al.*, 1997) and the Fas antibody (Bajt *et al.*, 2000) or could be just the result of detachment from the extracellular matrix (Ito *et al.*, 2006). In general, matrix metalloproteinase inhibitors prevent the gap formation (McCuskey, 2006a). A consequence of endothelial cell injury is the loss of barrier function with extensive blood accumulation in the liver resulting in hypovolemic shock. Microcystin produces this effect within hours in rodents (Hooser *et al.*, 1989). Microcystin dramatically deforms hepatocytes by altering cytoskeleton actin filaments, but it does not affect sinusoidal cells (Hooser *et al.*, 1991). Thus, the deformities that microcystin produces on the cytoskeleton of hepatocytes likely produce a secondary change in the structural integrity of the sinusoid owing to the close proximity of hepatocytes and sinusoidal endothelial cells (Fig. 13-2).

Progressive destruction of the endothelial wall of the sinusoid will lead to gaps and then ruptures of its barrier integrity, with entrapment of red blood cells. These disruptions of the sinusoid are considered the early structural features of the vascular disorder known as veno-occlusive disease (DeLeve *et al.*, 1999). Well established as a cause of veno-occlusive disease are the pyrrolizidine alkaloids (eg, monocrotaline, retrorsine, and seneciphylline) found in some plants used for herbal teas and in some seeds that contaminate food grains. Numerous episodes of human and animal poisoning by pyrrolizidine alkaloids have been reported around the world, including massive problems affecting thousands of people in Afghanistan in 1976 and 1993 (Huxtable, 1997). Venocclusive disease is also a serious complication in about 15% of the patients given high doses of chemotherapy (eg, cyclophosphamide) as part of bone-marrow transplantation regimens (DeLeve *et al.*, 1999).

Selective depletion of GSH within sinusoidal endothelial cells and activation of matrix metalloproteinases are critical events in the mechanism of endothelial cell injury in the pathophysiology of veno-occlusive disease (Wang *et al.*, 2000; DeLeve *et al.*, 2003b). Endothelial cell gap formation and injury and the resulting microcirculatory disturbances have been well established as the cause of veno-occlusive disease (DeLeve *et al.*, 2003a).

Disruption of the Cytoskeleton Phalloidin and microcystin disrupt the integrity of hepatocyte cytoskeleton by affecting proteins that are vital to its dynamic nature. The detrimental effects of these two potent hepatotoxicants are independent of their biotransformation and are exclusive for hepatocytes, because there is no appreciable uptake of either toxin into other types of cells. Tight binding of phalloidin to actin filaments prevents the disassembly phase of the normally dynamic rearrangement of the actin filament constituent of the cytoskeleton. Phalloidin uptake into hepatocytes leads to striking alterations in the actin-rich web of cytoskeleton adjacent to the canalicular membrane; the actin web becomes accentuated and the canalicular lumen dilates (Phillips *et al.*, 1986). Experiments using time-lapse video microscopy have documented dose-dependent declines in the contraction of canalicular lumens between isolated hepatocyte couplets after incubation with a range of phalloidin concentrations (Watanabe and Phillips, 1986).

Microcystin uptake into hepatocytes leads to hyperphosphorylation of cytoskeletal proteins secondary to this toxicant's covalent binding to the catalytic subunit of serine/threonine protein phosphatases (Runnegar *et al.*, 1995b). Reversible phosphorylations of cytoskeletal structural and motor proteins are critical to the dynamic integrity of the cytoskeleton. Extensive hyperphosphorylation produced by large amounts of microcystin leads to marked deformation of hepatocytes due to a unique collapse of the microtubular actin scaffold into a spiny central aggregate (Hooser *et al.*, 1991). Lower doses of microcystin, insufficient to produce the gross structural deformations, diminish uptake and secretory functions of hepatocytes in association with preferential hyperphosphorylation of the cytoplasmic motor protein dynein (Runnegar *et al.*, 1999). Dynein is a mechanochemical protein that drives vesicles along microtubules using energy from ATP hydrolysis; central to the hydrolysis of the dynein-bound ATP is a cycle of kinase phosphorylation and phosphatase dephosphorylation. Thus, hyperphosphorylation of dynein freezes this motor pump. Chronic exposure to low levels of microcystin has raised new concerns about the health effects of this water contaminant. Specifically, low levels of microcystin promote liver tumors and kill hepatocytes in the zone 3 region, where microcystin accumulates (Solter *et al.*, 1998).

Information about the binding of phalloidin and microcystin to specific target molecules is valuable for two reasons. First, the linkages of specific binding to loss of target protein functions provide compelling evidence that such a binding constitutes a defined molecular mechanism of injury. Second, the demonstrations of high-affinity binding to a target molecule without confounding effects on other processes or tissues have *translated* into applications of these toxins as tools for cell biology research. For example, phalloidin complexed with a fluorochrome (eg, rhodamine phalloidin or Texas Red phalloidin) is used to visualize the actin polymer component of the cytoskeleton in all types of permeabilized cells. The collapse of actin filaments into spiny aggregates after microcystin treatment was visualized by fluorescence microscopy of cells stained with rhodamine phalloidin (Hooser *et al.*, 1991). Low levels of microcystin are being used to discriminate the roles of dynein from other cytoskeletal motor proteins (Runnegar *et al.*, 1999).
